(Received 7 March 2002; revised manuscript received 27 June 2002; published 30 October 2002)

The $a$-$b$-plane reflectance of a Pr$_2$CuO$_4$ single crystal has been measured over a wide frequency range at a variety of temperatures, and the optical properties determined from a Kramers-Kronig analysis. Above $\approx 250$ K, the low-frequency conductivity increases quickly with temperature; $\rho_{dc} \approx 1/\sigma_\omega (\omega \rightarrow 0)$ follows the form $\rho_{dc} \approx \exp(E_u/\kappa_B T)$, where $E_u \approx 0.17$ eV is much less than the inferred optical gap of $\approx 1.2$ eV. Transport measurements show that at low temperature the resistivity deviates from activated behavior and follows the form $\rho_{dc} \approx \exp(T_0/T)^{1/4}$, indicating that the dc transport in this material is due to variable-range hopping between localized states in the gap. The four infrared-active $E_u$ modes dominate the infrared optical properties. Below $\approx 200$ K, a striking new feature appears near the low-frequency $E_u$ mode, and there is an additional new fine structure at high frequency. A normal coordinate analysis has been performed and the detailed nature of the zone-center vibrations determined. Only the low-frequency $E_u$ mode has a significant Pr-Cu interaction. Several possible mechanisms related to the antiferromagnetism in this material are proposed to explain the sudden appearance of this and other new spectral features at low temperature.

I. INTRODUCTION

Within the family of high-temperature cuprate superconductors, the Ce-doped series $R_{2-x}$Ce$_x$CuO$_{4-x}$, where $R =$Nd, Sm, Eu, Gd, etc., are the only materials which appear to be electron doped. The undoped Nd$_2$CuO$_4$ and Pr$_2$CuO$_4$ are antiferromagnetic insulators, which become “bad metals” with Ce doping until the sudden onset of superconductivity at $x \approx 0.14$. The region of superconductivity in the electron-doped materials is quite narrow ($x \approx 0.14$–0.18). There is essentially no “underdoped” region, respectively, occurring at $x \approx 0.15$. At higher dopings $T_c$ decreases rapidly, vanishing above $x \approx 0.18$. At the solubility limit ($x = 0.22$) the Nd system is metallic with no evidence of superconductivity.

The optimally doped systems become superconducting only after oxygen reduction ($\delta \approx 0.01$–0.03), and some transport measurements suggest that both electrons and holes participate in the charge transport in the superconducting phase. The role played by oxygen in these materials may be more complex than in the hole-doped cuprates. It is the interesting behavior of these superconducting systems that motivates an examination of the optical properties of one of the parent compounds, Pr$_2$CuO$_4$.

The $T'$ structure of Pr$_2$CuO$_4$ is similar to the $T$ structure of the hole-doped La$_{2-x}$Sr$_x$CuO$_4$; both structures are body-centered tetragonal, space group $I4mm$ (D$_{4h}$) (Ref. 10). These materials consist of two-dimensional sheets of copper-oxygen layers, which define the $a$-$b$ planes, with the $c$ axis being perpendicular to the planes. The $T$ and $T'$ structures differ in the location of the oxygen atoms between the copper-oxygen sheets. In the $T$ structure the copper atoms have octahedral coordination, surrounded by four oxygen atoms in the $a$-$b$ plane and two apical oxygens along the $c$ axis. However, in the $T'$ structure shown in Fig. 1, the apical sites are empty, and the out-of-plane oxygen atoms are not chemically bonded to the copper atoms in the planes, which, as a result, have a square coordination. While the difference between the $T$ and $T'$ structures results in different Raman-active modes, the same number of infrared-active modes $3A_{2u} + B_{2u} + 4E_u$ are expected for each. The doubly degenerate $A_{2u}$ modes are active in the $a$-$b$ planes, the singly degenerate $A_{2u}$ modes are active only along the $c$ axis, and the $B_{2u}$ mode is silent.

The strong Cu-O bonding in the $a$-$b$ plane of this material gives rise to two-dimensional electronic and magnetic behaviors. The weak out-of-plane coupling induces long-range antiferromagnetic (AFM) order in the Cu spins at the relatively modest temperature of $T_{N,Cu} \approx 250$–280 K (Refs. 12–14), which is similar to the values of $T_{N,Cu} \approx 250$–300 K observed in Nd$_2$CuO$_4$ (Refs. 13 and 15), Eu$_2$CuO$_4$ (Ref. 16), and La$_2$CuO$_4$ (Refs. 17 and 18). The rare-earth Pr ions carry localized 4f moments, which typically order at very low temperatures. However, from symmetry considerations, the Pr moments should order below $T_{N,Cu}$ in this material. In fact, due to the significant exchange interactions between the Pr ions, which are mediated through the copper-oxygen layers, there is a Pr contribution to the susceptibility below $\approx 200$ K.

The optical properties of Nd$_2$CuO$_4$ have been investigated in ceramics and single crystals. Single crystals of Pr$_2$CuO$_4$ have been studied at either room temperature or at low temperatures ($\approx 10$ K), but there has been no

0163-1829/2002/66(14)/144511(9)/$20.00 66 144511-1 ©2002 The American Physical Society
detailed investigation of the temperature dependence of the optical properties of this material. Furthermore, there is some disagreement in the literature with respect to the vibrational parameters of the $E_u$ modes. 

In this paper we report on the detailed optical properties of Pr$_2$CuO$_4$ at a variety of temperatures. The conductivity at low frequency has a strong temperature dependence above room temperature, which when taken with optical estimates of the gap suggests that the transport is due to variable-range hopping due to localized states in the gap. Transport measurements support this conclusion. A strong new vibration appears close to the low-frequency $E_u$ mode below about 200 K, in addition to other weak vibrational structure. A normal coordinate analysis of the zone-center vibrational modes indicates that of all the $E_u$ modes, only the low-frequency mode involves a significant Pr-Cu interaction. It is proposed that the AFM order in this material is responsible for the lifting of the degeneracy of the low-frequency $E_u$ mode; the absence of any interaction between the Pr and Cu atoms in the other $E_u$ modes limits this effect to just the low-frequency $E_u$ mode.

**II. EXPERIMENT**

Single crystals of Pr$_2$CuO$_4$ were grown using a CuO-based direction solidification technique. The crystals are thin platelets $\approx 1.5 \times 1.5$ mm$^2$ in the $a$-$b$ plane, but quite thin along the $c$ axis ($\approx 50$ μm). The crystals examined had a flat, mirrorlike surface that was free of flux or other residue. Transport and optical measurements were performed on the same sample for consistency. The measurements of resistivity in the $a$-$b$ plane were carried out using standard four-probe configuration. Gold wires were attached to the specimen directly using silver-loaded epoxy and followed by a spot annealing at the contacts with focused laser beam. The whole specimen remained at room temperature, except the $; 70$-μm-wide areas surrounding the contacts. This process generally resulted in a contact resistance less than 1 Ω. With such a low contact resistance, without changing the oxygen content in these samples, we were able to measure the resistivity over six orders of magnitude from 90 K to 340 K with high accuracy $\approx$ better than 0.1%, shown in Fig. 2. The inset shows the resistivity vs the inverse temperature; the linear response at high temperature is an indication of activated behavior, although this is no longer the case for $T < 160$ K.

Magnetization measurements were performed on an unoriented 2-mg crystal of Pr$_2$CuO$_4$ in an MPMS magnetometer at an applied field of 5 T. The behavior of $1/X_M$ follows a Curie-Weiss form, and linear regression yields a Neel temperature for Pr of $T_{N,Pr}=44$ K, with a Pr magnetic moment of $3.2\mu_B$. A careful survey of the temperature region in which the antiferromagnetic ordering of copper moments is expected (200 K $< T_{N,Cu} < 320$ K) reveals no apparent anomaly in the magnetization. A feature comparable in size and definition to that observed by Sun et al. for La$_2$CuO$_4$ would have been readily observable. However, based on the scatter in our data, an antiferromagnetic anomaly reduced in

![FIG. 1. The unit cell of the Pr$_2$CuO$_4$ in the $I4/mmm$ space group showing the square planar coordination of the Cu-O(1) layers, as well as the corrugated structure of the Pr-O(2) layers. The unit-cell dimensions are $a=b=3.943$ Å and $c=12.15$ Å (Ref. 14).](144511-2)
size by more than 50% and/or smeared over a larger temperature region might not be discernible. It is worth noting that the majority of studies of the ordering of the Cu spins in these materials have been neutron-scattering measurements on substantially larger samples than the ones examined in this work.

For the optical measurements, crystals were mounted in a cryostat on an optically black cone. The temperature dependence of the reflectance was measured at a near-normal angle of incidence from \( \approx 30 \) to over 16000 cm\(^{-1} \) on a Bruker IFS 66v/S using an *in situ* overcoating technique, which has previously been described in detail elsewhere.\(^{34} \) This technique is especially useful when measuring small samples, as it allows the entire face of the sample to be utilized. Above \( \approx 5000 \) cm\(^{-1} \), the reflectance is assumed to be temperature independent.

The optical conductivity has been determined from a Kramers-Kronig analysis of the reflectance, for which extrapolations for \( \omega \rightarrow 0, \infty \) must be supplied. At low frequency, a metallic extrapolation was used for \( T \leq 260 \) K, \( R \approx 1 - \sqrt{\omega} \), while below this temperature, the reflectance was assumed to continue smoothly to \( \approx 0.45 \) at zero frequency. At high frequency, the reflectance was assumed to be constant above the highest measured frequency point to \( 2 \times 10^5 \) cm\(^{-1} \), above which a free-electron (\( R \approx \omega^{-4} \)) behavior was assumed. At low temperature, the semitransparent nature of the sample has implications for the Kramers-Kronig analysis, which assumes specular reflectance from a single surface only. While the absorption due to the lattice modes assures that the reflectance in those regions is essentially that of the bulk material, the same cannot be said for the high-frequency region. The presence of multiple reflections leads to asymmetries in the line shapes and an optical conductivity less than zero. As a result, for the calculation of the low-frequency conductivity in the region of the lattice modes, the reflectance has been truncated at \( \approx 3000 \) cm\(^{-1} \) and assumed to be constant only up to 8000 cm\(^{-1} \), above which a free-electron approximation has been assumed. While the line shapes in the conductivity are symmetric Lorentzians whose positions and widths do not vary greatly with different choices for the high-frequency extrapolations, the amplitudes are somewhat sensitive upon this choice.

### III. RESULTS

The reflectance of \( \text{Pr}_2\text{CuO}_4 \) for light polarized in the \( a-b \) plane is shown in Fig. 3 from \( \approx 20 \) to 1500 cm\(^{-1} \) at a variety of temperatures, and in the inset from \( \approx 30 \) to 16000 cm\(^{-1} \) at room temperature. The reflectance at low frequency is dominated by structure due to the normally active infrared modes, while the reflectance at high frequency is relatively featureless, except for some structure at \( \approx 11000 \) cm\(^{-1} \). The low-frequency vibration at \( \approx 130 \) cm\(^{-1} \) is observed to be a single mode at room temperature. However, at low temperature, this mode is resolved as a doublet. The low-frequency reflectance has an interesting behavior; at low temperature the fringes indicate a lack of absorption due to the insulating nature of the sample, but at room temperature and above the fringes have vanished and the reflectance appears to be tending towards unity as \( \omega \rightarrow 0 \); at 390 K the low-frequency reflectance is over 80% and the system appears to be weakly metallic.

The optical conductivity \( \sigma_\omega(\omega) \) calculated from a Kramers-Kronig analysis of the reflectance at 295 K is shown in Fig. 4. The low-frequency conductivity is dominated by the infrared-active \( E_u \) lattice modes, but a careful examination shows a slight asymmetry in the line shape of the strongest mode. The weak feature observed in the reflectance at \( \approx 11000 \) cm\(^{-1} \) signals the onset of absorption in the conductivity at about 9000 cm\(^{-1} \), which peaks at about 12000 cm\(^{-1} \). The optical conductivity in the region of the infrared-active modes calculated using the truncated reflectance is shown in the inset of Fig. 3. The modes have symmetric profiles, and all the three high-frequency modes harden and narrow with decreasing frequency.
A new feature appears quickly below room temperature, gaining oscillator strength monotonically with decreasing temperature. The inset in Fig. 5 shows the extrapolated value of the resistivity \( \rho_{dc} \approx \frac{1}{\sigma_T(\omega \to 0)} \) vs \( 1/T \) (\( T \geq 250 \text{ K} \)); the linear behavior indicates that the conductivity is strongly activated.\(^{35}\)

The behavior of the low-frequency mode is seen clearly in a more detailed plot of the \( a-b \)-plane reflectance shown in Fig. 6 and the conductivity in upper inset. The low-frequency conductivity is shown in detail in Fig. 4 to the linear part of the leading edge conductivity in Fig. 4 to the linear part of the leading edge conductivity, where \( E_a = 1630 \pm 200 \text{ cm}^{-1} \) (\( \approx 0.2 \text{ eV} \)).

\[ \rho_{dc} \propto e^{E_a/k_B T}, \]

where \( E_a \) is either the half the optical gap \( 2\Delta \), or half the polaronic level shift \( E_p \). The low-frequency reflectance increases quickly above room temperature, which is indicative of a "metallic" response in which the reflectance goes to unity at zero frequency. This observation is realized in the optical conductivity, where \( \sigma_{dc} = \sigma_T(\omega \to 0) \) has a very strong temperature dependence for \( T \geq 300 \text{ K} \). The plot of \( \rho_{dc} = \frac{1}{\sigma_{dc}} \) vs \( 1/T \) is shown in the inset in Fig. 5, and is described quite well by Eq. (1); a linear regression yields \( E_a = 1630 \pm 200 \text{ cm}^{-1} \) (\( \approx 0.2 \text{ eV} \)). The rather large error associated with this estimate is due to the fact that the fit is limited to a narrow interval in the high-temperature region. The transport data shown in Fig. 2 and the inset are also described quite well by activated behavior; a linear regression applied in the high-temperature region (\( T \geq 160 \text{ K} \)) yields \( E_a = 1380 \pm 50 \text{ cm}^{-1} \) (\( \approx 0.17 \text{ eV} \)), and is shown as a dashed line in the inset of Fig. 2; this value for \( E_a \) is fairly close to the value determined from the optical conductivity. The optical conductivity of the nickelates, which have a similar appearance, has been fitted using a small-polaron model,\(^{37-39}\) which for \( T \gg \omega/2 \) produces an asymmetric Gaussian peak with a maximum at \( 4E_a \). This model would imply that the peak in the conductivity at high temperature should occur at \( \approx 6000 \text{ cm}^{-1} \), which is much less than the observed value of \( \approx 12500 \text{ cm}^{-1} \). A rough estimate of the direct optical gap may be made by extrapolating from the linear part of the leading edge conductivity in Fig. 4 to the abscissa, which gives \( 2\Delta \approx 9500 \text{ cm}^{-1} \). If the transport were due to the carrier pair density from thermal excitations across the gap, then \( \sigma_{dc} \propto n \propto \exp(-\Delta/k_BT) \). However, \( E_a \ll \Delta \), suggesting that the dc transport is due to variable-range hopping
between localized states within the gap. At low temperatures, the resistivity due to hopping is not activated, but instead has the form

$$\rho_{dc} \propto e^{(T_0 / T)^{1/n}}$$

where $T_0$ is a characteristic temperature, and $n = d + 1$, where $d$ is the dimensionality of the system. The transport measurements have been performed over a range wide enough so that the departure from activated to power-law behavior at low temperature is clearly visible in the inset in Fig. 2. Different power laws were examined, but it appears that the resistivity at low temperature is well described by $\rho_{dc} \propto \exp[(T_0 / T)^{1/n}]$, suggesting that the hopping is a three-dimensional rather than a two-dimensional phenomena restricted to the CuO$_2$ planes. The localized states that result in hopping may arise from defects that produced states within the gap. There is a very weak feature in the optical conductivity in Fig. 4 at $\sim 8000$ cm$^{-1}$, which occurs at $\sim E_g$ below the leading edge of the absorption. This feature may suggest a possible origin for the localized states. However, it is not clear whether the defects states responsible for this feature are an intrinsic property of the sample, or they are due to extrinsic effects.

**B. Vibrational properties**

1. **Normal coordinate analysis of the lattice modes**

The unusual behavior of the low-frequency $E_u$ mode requires a detailed understanding not only of the nature of this particular mode, but of the other $E_u$ modes as well. For this reason, a normal coordinate analysis of Pr$_2$CuO$_4$ was undertaken. The normal coordinate calculations were performed using Wilson’s GF matrix method and a commercially available software package. Initially, a simple valence force field was adopted, consisting of bond-stretching and angle-bending coordinates; the types and values of the force constants used, and the internal coordinates to which they correspond are listed in Table II. The force field involves six bond-stretching force constants and four angle-bending force constants. The bond stretch and angle bends all involve oxy-

**TABLE I.** The results of fitting the phonon parameters to the reflectance of Pr$_2$CuO$_4$ for light polarized in the $a$-$b$ plane at 295, 200, and 15 K, using the model for a lamellar plate. Several overdamped Lorentzian oscillators have been included in the fits to reproduce the broad, incoherent absorption attributed to thermally activated hopping. At room temperature the Drude component (a Lorentzian centered at zero frequency) is $\gamma_0 = 420$ and $\omega_{p,0} = 620$. The parameters for the two mid-infrared bands are $\omega_1 = 1100$, $\gamma_1 = 1120$, and $\omega_{p,1} = 1270$; $\omega_e = 4400$, $\gamma_2 = 1800$, and $\omega_{p,2} = 2200$. (All units are in cm$^{-1}$). A thickness of $d = 50$ $\mu$m and $\epsilon_r = 6.5$ have been assumed. The parameters $\omega_{TO,1}$, $\gamma_1$, and $\omega_{p,1}$ refer to the frequency, width, and effective plasma frequency of the $i$th vibration. [All units are in cm$^{-1}$, except for the dimensionless oscillator strength $S_i = \omega_{p,i}^2 / \omega_{TO,i}^2$.]

placements of the O atoms in the Pr-O layers; interestingly, this mode has a significant coordination between the displacements of the Pr atoms and the Cu and O(1) atoms, indicated in Table III. The PED’s give the relative contribution of the force constants to the potential energy of the normal modes. This treatment yields the atomic displacements and PED’s for all of the normal modes. Each of the in-plane infrared-active $E_u$ modes merit’s further discussion.

The $E_u$ mode at 490 cm$^{-1}$ at room temperature involves primarily the in-plane Cu-O angle bending resulting in displacements of the O(1) atoms. In addition, there are small displacements of the atoms in the Pr-O(2) planes; the motions of the Pr and O(1) atoms are coordinated. However, as Table III shows, there is no interaction between the rather small Pr and the Cu displacements. In general, the eigenvectors determined from the normal coordinate analysis are in good agreement with the calculated zone-center displacements shown in Ref. 22. This mode hardens to 495 cm$^{-1}$ at 15 K and narrows dramatically from $\approx 25$ to $\approx 8$ cm$^{-1}$, as shown in Table I. The oscillator strength of this mode does not vary with temperature. The slight asymmetry that is observed in the optical conductivity of the high-frequency $E_u$ mode in Fig. 4 is most likely produced by the uncertainty in the high-frequency extrapolation used in the Kramers-Kronig analysis; fits to the reflectance are exact and do not suggest a large asymmetry in this feature or others (the Appendix).

The mode at 331 cm$^{-1}$ is a pure Pr-O(2) bond stretch, while the 304-cm$^{-1}$ mode is almost a pure Cu-O(1) bond stretch (Table III). The mode at 331 cm$^{-1}$ hardens considerably to 341 cm$^{-1}$ at 15 K, and also narrows from $\approx 17$ to 3.4 cm$^{-1}$. The mode at $\approx 304$ cm$^{-1}$ hardens only slightly with decreasing temperature, but narrows significantly from $\approx 8$ cm$^{-1}$ at room temperature to 1.4 cm$^{-1}$ at 15 K; this is the strongest $E_u$ mode with an oscillator strength of $S \approx 7.4$.

The mode at 130 cm$^{-1}$ is a combination of Cu-O angle bending, resulting in the in-plane displacements of the Cu and O(1) atoms, as well as the out-of-phase motion of the Pr and O(2) atoms in the Pr-O layers; interestingly, this mode has a significant coordination between the displacements of the Pr atoms and the Cu and O(1) atoms, indicated in Table III. The only other mode that has a strong Pr-Cu interaction is the low-frequency $c$-axis $A_{2g}$ mode. The low-frequency $E_u$ mode softens to $\approx 128$ cm$^{-1}$ at low temperature, while narrowing. The observed frequencies are in good agreement with previous work, however, the linewidths are all narrower and there is only rough agreement with the reported strengths.

2. Origin of the low-temperature doublet at $\approx 130$ cm$^{-1}$

The most unusual feature in the reflectance spectra is the striking appearance of a new mode at low temperature, which is just above the low-frequency $E_u$ mode. The new mode is not simply a peculiar artifact due to fringes in the presence of vibrational structure, as Fig. 7(b) demonstrates (the Appendix). While this feature has been previously observed at low temperature, the evolution of this new mode has, to our knowledge, never been studied or fully explained. The new feature appears suddenly below $\approx 250$ K at $\approx 140$ cm$^{-1}$, as seen in Fig. 6 and in the insets; this mode hardens dramatically and narrows with decreasing temperature, gaining strength monotonically until it has almost the same oscillator strength as the low-frequency $E_u$ mode (Table I). This feature does not appear to evolve from a strong asymmetry or shoulder in the low-frequency $E_u$.

$^b$The observed frequencies for the $A_{2u}$ modes are taken from Ref. 29, while the Raman-active modes are taken as those for Nd$_2$CuO$_4$ from Ref. 48. The frequencies for the $E_u$ modes are from this work (Table I).

$^b$See Table II for the identification of the force constants.
mode. There is also an additional very weak new fine structure in the low-temperature reflectance at \( \approx 541 \) and 688 cm\(^{-1} \). These frequencies are well above the high-frequency \( E_u \) mode at \( \approx 490 \) cm\(^{-1} \). A symmetry-breaking process would allow the Raman-active modes as well as the longitudinal-optic (LO) modes to become weakly active. However, the highest observed frequency for a Raman mode is the \( E_g \) mode at \( \approx 480 \) cm\(^{-1} \), suggesting that these features are not Raman modes. To determine the positions of the LO modes, the reflectance and optical conductivity have also been fitted using a factorized form of the dielectric function\(^{46} \)

\[
\tilde{\varepsilon}(\omega) = \varepsilon_\infty \prod_j \frac{\omega_{LO,j}^2 - \omega^2 - i \gamma_{LO,j} \omega}{\omega_{TO,j}^2 - \omega^2 - i \gamma_{TO,j} \omega},
\]

where \( \omega_{LO,j}, \omega_{TO,j}, \gamma_{LO,j}, \) and \( \gamma_{TO,j} \) are the \( j \)th LO and the normally active transverse optic (TO) modes, and LO and TO dampings, respectively. The fit at 15 K yields values for the TO modes which are nearly identical to those shown in Table I, and LO modes at 131, 149, 332, 430, and 588 cm\(^{-1} \), respectively. None of the LO modes are close to the new features observed at low temperature, making it unlikely that any new structure is due to the LO modes.

A more promising explanation of the splitting of the low-frequency mode may involve the fact that of all the \( E_u \) modes, only the low-frequency mode involves a significant Pr-Cu interaction. Magnetization measurements in this work show that the Pr atoms are ordered at low temperatures (\( \leq 50 \) K), and neutron-scattering measurements\(^{14} \) show that there is at least a partial ordering at higher temperatures, indicating the presence of a Pr-Cu exchange interaction. In the case of the low-frequency \( E_u \) mode, the displacements of the Pr and Cu atoms are strongly correlated, suggesting that the exchange interaction will have a significant effect upon the nature of this vibration. This can lead to a symmetry-breaking process and the splitting of the doubly degenerate \( E_u \) mode. This view is consistent with the observation that this new feature is not present in \( Pr_{1.85}Ce_{0.15}CuO_4 \), which is in the region of the phase diagram for this class of materials where the AFM order is destroyed.\(^{21} \) Because the other \( E_u \) modes do not involve strong Pr-Cu coupling, no exchange-induced splitting would be expected. In fact, of all the other vibrational modes, only the low-frequency \( A_{2u} \) mode has a significant Pr-Cu interaction (Table III); but since this mode is singly degenerate, no splitting is expected, nor is it observed.\(^{32} \) Similar behavior might also be expected in \( Nd_2CuO_4 \), where the Nd moments order below 37 K. In fact, a weak feature is observed in the reflectance of \( Nd_2CuO_4 \) at 10 K and at \( \approx 165 \) cm\(^{-1} \), quite close to the low-frequency \( E_u \) mode, and it has been suggested that this feature is indeed magnetic in origin.\(^{21} \) Kramers doublets have also been reported in the Raman spectra at low temperature,\(^{47} \) which have been attributed to the removal of degeneracy by the Nd-Cu exchange interaction.\(^{48} \) While this is a reasonable explanation for the strong feature at low frequency, it is less satisfactory for the fine structure observed at high frequency.

The new structure observed at \( \approx 688 \) cm\(^{-1} \) at low temperature is similar in frequency to the structure that has been observed in other electron-doped materials\(^{27,49} \) at \( \approx 690 \) cm\(^{-1} \). It has been suggested that many of the fine structures observed in the cuprate systems are local vibrational modes due to polaron fine structure.\(^{27,50} \) Alternatively, a number of weak features are also seen below the Néel transition in CuO, including a mode at \( \approx 690 \) cm\(^{-1} \), which has been attributed to the activation of a zone-boundary mode due to the reduction of the Brillouin zone resulting from the magnetic order.\(^{51,52} \) It is possible that the magnetic order is responsible for a weak structural distortion and the activation of the zone-boundary modes due to the commensurate reduction of the Brillouin zone. However, a difficulty with this explanation is that any reduction of the Brillouin zone should result in a number of new modes being activated, rather than just the three that are observed. One of the difficulties in explaining the vibrational fine structure observed in this system is the failure to observe these results on a consistent basis in different studies.\(^{27,53} \) This raises the distinct possibility that some of these features arise from impurities and/or phase separation, ultimately making it difficult to identify a specific mechanism responsible for the origin of the fine structure.

V. CONCLUSIONS

The strong temperature dependence of the low-frequency reflectance above \( \approx 250 \) K results in a resistivity \( \rho_{dc} \).
the resistivity show a departure from activated behavior for
E u prominent feature close to the low-frequency has been performed to provide a detailed understanding of
cussion of the lattice modes. A normal coordinate analysis
T N below is observed at high frequency. These new features appear
v e slightly lower and more accurate value of 
v a. The fact that the transport gap E a is much less than the inferred
tical gap 2Δ ≈ 1.2 eV, and that transport measurements of
show a departure from activated behavior for
T ≤ 160 K to a ρdc ∝ exp[(T0/T)1/2] power-law behavior sug-
gests that the transport in this material is due to variable-
range hopping between localized states in the gap.

Due to the unusual vibrational structure in Pr2CuO4 at
low temperature, considerable attention was devoted to a dis-
cussion of the lattice modes. A normal coordinate analysis
has been performed to provide a detailed understanding of
the nature of the zone-center vibrations in this material. A
prominent feature close to the low-frequency Ea mode de-
velops at low temperature, and additional weak fine structure is
observed at high frequency. These new features appear
below Tκ,Cu at roughly the same temperature at which the Pr
moments are thought to begin to order (≈ 200 K). Only the
low-frequency Ea mode involves a significant Pr-Cu interac-
tion. This suggests that the new vibrational structure is due to
the antiferromagnetic order in this material and due to the
removal of degeneracy of this mode.

ACKNOWLEDGMENTS

We are grateful to A. R. Moodenbaugh for performing the
magnetization measurements. We would also like to thank D.
N. Basov, V. J. Emery, J. L. Musfeldt, M. Strongin, T. Ti-
musk, J. M. Tranquada, and J. J. Tu for many helpful discus-
sions. This work was supported by the Department of Energy
under Contract No. DE-AC02-98CH10886; the work in
Maryland was supported by the NSF Condensed Matter
Physics Division under Grant No. DMR 0102350. Research
undertaken at NSLS was supported by the US Department of
Energy, Division of Materials and Chemical Sciences.

APPENDIX: REFLECTANCE OF A DIELECTRIC SLAB

Due to the complications introduced by the slightly trans-
parent nature of the sample, the reflectance and the lattice
modes have been fit using a model that considers reflections
from both the front and back surfaces of the crystal. The
frequency-dependent reflectance of a lamellar plate at a nor-
mal angle of incidence is \( R = \frac{\tilde{r}^2}{\tilde{r}^2} \), where \( \tilde{r} \) is defined as

\[
\tilde{r} = \frac{1 - e^{-i4\pi nd}}{1 - e^{i4\pi nd}},
\]

(A1)

where \( d \) is the sample thickness and \( \tilde{r} \) is the Fresnel reflect-
ance of the bulk material.

The complex refractive index is \( \tilde{n} = n + ik \), which is re-
lated to the complex dielectric function \( \varepsilon = \varepsilon_1 + i\varepsilon_2 = \tilde{n}^2 \), al-
lowing the real and imaginary parts of the refractive index \( n \) and \( k \) to be determined

\[
n = \frac{1}{2} \left( \sqrt{\varepsilon_1^2 + \varepsilon_2^2 + \varepsilon_1} \right)^{1/2},
\]

(A3)

\[
k = \frac{1}{2} \left( \sqrt{\varepsilon_1^2 + \varepsilon_2^2 - \varepsilon_1} \right)^{1/2}.
\]

(A4)

The optical properties of the bulk material are modeled using
a series of Lorentzian oscillators,

\[
\tilde{\varepsilon}(\omega) = \varepsilon_\infty + \sum_{j} \frac{\omega_{p,j}^2}{\omega_j^2 - \omega^2 - i\gamma_j \omega},
\]

(A5)

where \( \omega_j, \gamma_j, \) and \( \omega_{p,j} \) are the frequency, width, and effec-
tive plasma frequency of the \( j \)th vibration; and \( \varepsilon_\infty \) is the core
contribution to the dielectric function. The dimensionless os-
cillator strength is written as \( S_j = \omega_{p,j}^2 / \omega_j^2 \). The optical con-
ductivity \( \tilde{\sigma}(\omega) = \sigma_1(\omega) + i\sigma_2(\omega) \) is related to the complex
dielectric function by \( \tilde{\sigma}(\omega) = -i\omega\varepsilon(\omega)/4\pi \).

The phonon parameters were refined by a nonlinear least-
squares fit of the model for the reflectance of a thin dielectric
slab to the experimental reflectance in Fig. 3. The results at
295, 200, and 15 K are listed in Table I, and a comparison of
the experimental reflectance and the model results are shown
in Figs. 7(a) and 7(b) at 295 and 15 K, respectively. The
broad, incoherent electronic background observed at room
temperature is modeled by a zero-frequency Drude term, as
well as two mid-infrared overdamped oscillators (Table I).
The results were then compared with fits to the features in
the conductivity by assuming simple linear background in
the region of the lattice modes, and were found to be in good
agreement. This indicates that in the region of the phonon
features where the sample is opaque, the Kramers-Kronig
relation yields acceptable values for the conductivity.
