Mesoscale convective systems (MCSs) are complexes of thunderstorms that become organized and cover hundreds of kilometers over several hours. MCSs are prolific rain producers in the tropics and mid-latitudes and are the major cause of warm-season flooding. Traditionally, climate models have difficulties in simulating MCSs partly due to the misrepresentation of complex process interactions that operate across a large range of scales. Significant improvements in simulating MCSs have been found in kilometer-scale models that explicitly simulate deep convection. However, these models operate in the grey zone of turbulent motion and have known deficiencies in simulating small-scale processes (e.g., entrainment, vertical mass transport). Here, we perform mid-latitude idealized ensemble MCS simulations under current and future climate conditions in three atmospheric regimes: hydrostatic (12 km horizontal grid spacing; Δx), non-hydrostatic ($\Delta x=4, 2$, and 1 km), and large-eddy-scale ($\Delta x=500$ m and 250 m). Our results show a dramatic improvement in simulating MCS precipitation, movement, cold pools, and cloud properties when transitioning from 12 km to 4 km Δx . Decreasing Δx beyond 4 km results in modest improvements except for up- and downdraft sizes, average vertical mass fluxes, and cloud top height and temperature, which continue to change. Most important for climate modeling is that $\Delta x=4$ km simulations reliably capture most MCS climate change signals compared to those of the $\Delta x=250$ m runs. Significantly different climate change signals are found in $\Delta x=12$ km runs that overestimate extreme precipitation changes by up to 100%.

1. Introduction

Mesoscale convective systems (MCSs) play an important role in the earth's energy balance [19,61] and are essential for the water cycle in the tropics [31] and mid-latitude regions [12,14]. These systems are prolific rain producers and are the main cause of warm-season flooding [33,45]. Observations of MCSs over the continental U.S. indicate that extreme precipitation rates associated with MCSs have significantly increased since the 1980s [12], and MCSs are projected to further intensify under future climate change scenarios [39]. A major bottleneck for predicting possible climate change effects on future extremes is that convective storms and storm intensity (precipitation, updraft strength) are poorly represented by state-of-the-art models [22]. These challenges are exacerbated for MCS that represent some of the largest and most impactful of convective storms. This is because MCSs entail processes that operate and interact across a wide range of scales, which makes them hard to constrain with limited observations [19,30]. Improving MCS modeling capabilities is essential to advance the credibility of weather predictions and climate projections, especially for socioeconomic impactful extreme events (e.g., floods, droughts).

The frontier of global and regional atmospheric modeling has reached convection-permitting scales (horizontal grid spacings $\Delta x \leq 4$ km) [37]. Convection-permitting models (CPMs) can explicitly represent deep convection, which revolutionizes our ability to simulate and predict the weather and climate system [7,37]. CPMs substantially improve the simulation of MCSs including their propagation, evolution, size, and associated extreme precipitation [38]. This paper provides a multi-scale analysis of why this is true. An ongoing challenge of kilometer-scale modeling is that these models operate in the grey zone of turbulent motion, wherein convection is not fully resolved [60]. This causes challenges in realistically simulating cloud entrainment processes and draft characteristics [27].

Simulations in the turbulent grey zone truncate the turbulent energy spectrum, leading to misrepresentations of convection dynamics, which can result in a factor of two overestimation of convective updraft intensity in CPMs [10,55]. Moreover, the energy spectrum of deep convective clouds is continuous across kilometer to meter-scales, without an apparent energetic gap indicating a scale separation [15]. Thus, choosing an appropriate grid spacing to realistically simulate deep convective clouds is difficult, since spatial structures of turbulent motion do not converge until meter-scales [27]. Although turbulent motions are not fully resolved at the kilometer-scale [4], several studies have demonstrated that convergence of convective storm bulk properties (e.g., precipitation accumulations over a mesoscale region) can be achieved with kilometer-scale models [6,26,32,59]. A better understanding of the impacts of simulating in the grey zone is paramount since the climate community is rapidly transitioning to kilometer-scale grid spacings whereas large-eddy simulations on climate time scales are far out of reach [37].

In this study, we address two main research questions:

- (i) How are processes that interact within an MCS simulated across Δx spanning two orders of magnitude from hydrostatic-scales ($\Delta x=12$ km) to large-eddy-scales ($\Delta x=250$ m)?
- (ii) Which Δx is needed to reliably simulate MCS process changes under global warming?

The first question aims to identify systematic differences between large-eddy simulations ($\Delta x=250$ m) and grid spacings that are currently tested for regional and global climate modeling ($\Delta x=4$ km and $\Delta x=12$ km). The main objective is to investigate the convergence of bulk MCS properties. Identifying grid spacings that can reliably capture salient MCS properties such as total precipitation, vertical mass transport, and the cloud shield properties is important to capture the global energy budget and hydrologic cycle at efficient computational costs. The second question assesses the robustness of climate change signals comparing results from large-eddy simulations with simulations with grid spacings that are currently feasible for climate modeling.

50 The novel contribution of this study is the use of 10-member ensemble simulations in
51 current and future climate conditions under business as usual warming. Using an ensemble-
52 based approach allows investigating how systematic Δx dependent differences are to changes
53 in MCS inflow environments. Furthermore, we use a larger domain than previous studies,
54 enabling realistic simulation of three-dimensional MCSs, rather than MCS sections in a channel
55 configuration [5,27].

56 2. Data and Methods

57 The programs that were used for data processing and visualization in this paper are available on
58 GitHub [36].

59 (a) Initial Sounding for Idealized Simulations

60 The initial conditions for running idealized simulations are based on inflow soundings of air
61 that gets advected into heavy precipitating MCSs. The soundings are derived from two 13-
62 year long climate simulation covering most of North America under current and future climate
63 conditions [28]. Current and future climate simulations were performed using the Weather
64 Research and Forecasting (WRF) model [34,48] with a grid spacing of $\Delta x=4$ km. At this resolution,
65 deep convection can be explicitly represented in the model without the need for a deep
66 convection parameterization [37,59]. The current climate condition simulation downscales ERA-
67 Interim reanalysis data [9] within the period from October 2000 to September 2013. The future
68 simulation uses the pseudo global warming approach [28,40,44] by adding monthly climate
69 change perturbations to the 6-hourly boundary conditions of ERA-Interim during the same time
70 period. The perturbations are derived from an ensemble of CMIP5 (fifth phase of the Coupled
71 Model Intercomparison Project) global climate model projections [50]. These models use the
72 high-end representative concentration pathways (RCP8.5) comparing the period 2071–2100 to
73 1976–2005. More information about these $\Delta x=4$ km climate simulations are found in Liu et al.
74 (2017; [28]).

75 Inflow environmental conditions are derived from these simulations by using the identification
76 of MCSs from our previous study [38]. All MCSs that are identified in the central U.S. warm
77 season (June, July, and August; JJA) are ranked according to their peak hourly rainfall rate.
78 MCS inflow environments are derived from 3-hourly model level output and are defined as
79 the MCS relative upstream region that is perpendicular to the largest equivalent potential
80 temperature gradient [53,54]. Within the inflow environment, we search for grid cells that have
81 large maximum convective available potential energy (CAPE), low convective inhibition (CIN),
82 and large precipitable water in radial bands of 30 km centered on the location of maximum
83 precipitation with a maximum radius of 320 km. We excluded more distant sounding locations to
84 capture inflow air properties that are affecting the actual MCS development. The environmental
85 variables are calculated from mean air parcel condition (e.g., temperature, moisture) within a
86 depth of 500m centered on the maximum equivalent potential temperature level in the lowest
87 3 km above the surface. To exclude inflow grid-cells that are contaminated by the MCS or other
88 precipitating clouds, we remove all cells that are closer than 40 km to grid cells with precipitation
89 (precipitation rates $> 0.01 \text{ mm h}^{-1}$). These filtering steps retain several optimal inflow grid cells
90 for which various diagnostics are calculated (Supplementary Figure 1). We manually investigate
91 these diagnostics and select suitable soundings to initialize idealized WRF simulations.

92 (b) Model Setup

93 We use the WRF model version 3.9.1.1 to perform idealized MCS simulations. The source code
94 of WRF is available from GitHub (<https://github.com/wrf-model/WRF>). The model setup
95 is adapted from the WRF tutorial idealized case 3D supercell thunderstorm, which is called
96 em_quarter_ss [47]. A single sounding provides the initial and boundary conditions that are kept

97 constant over time. Domain size sensitivity tests showed that MCS features such as accumulated
98 precipitation start to converge at domain sizes of $600\text{ km}\times 600\text{ km}$ or larger (not shown). We use
99 95 vertical levels with an equal distance of 250 m similar to [27] and a 620 km square horizontal
100 domain. Limited sensitivity to decreases in vertical grid spacing has been shown for an idealized
101 squall line case [27]. We use open boundaries and apply Rayleigh damping to the top 20-levels of
102 the model domain to avoid wave reflections.

103 In all simulations, we neglect the effects of radiation, surface fluxes, Coriolis acceleration, and
104 do not use a planetary boundary layer scheme. Surface drag is included by applying the Eta
105 surface layer scheme [20], which helps to form coherent cold pools that organize convection. The
106 Thompson microphysics scheme is used [51], which was also applied in the climate simulations
107 from which the initial MCS inflow soundings are derived [28]. This scheme has been shown to
108 result in high-quality MCS simulations in the central U.S. [13]. The Kain-Fritsch deep convection
109 scheme [23] is only used in one of the $\Delta x=12\text{ km}$ simulations. In those simulations, we test the
110 effect of using the Kain-Fritsch deep convection closure [23] in addition to explicitly simulating
111 deep convection. An overview of the performed simulations is shown in Tab. 1.

112 All MCSs are simulated at six horizontal grid spacings: $\Delta x=12\text{ km}$, 4 km, 2 km, 1 km, 500 m,
113 and 250 m. At $\Delta x=250\text{ m}$, the model starts to resolve entrainment/detrainment [27]. Convection
114 is initiated by using a similar approach to previous work [27,62] by forcing vertical motion
115 within a half elliptic cylinder with a length of 40 km, a radius of 20 km and a depth of 4 km. The
116 flat side of the half-cylinder is located at the surface. We use a maximum vertical acceleration
117 of 2 m s^{-2} along the center of the cylinder. The acceleration decays with the cosine of the
118 radius. We randomly perturb potential temperature by 0.1 K in a rectangular area with a size of
119 $110\text{ km}\times 80\text{ km}\times 4\text{ km}$ centered on the half-cylinder to facilitate the development of 3D motion.
120 This approach is used in all simulations but the location of the half-cylinder was adjusted
121 depending on the MCS movement in each simulation to trigger convection close to the inflow
122 boundary to maximize the time before the MCS reaches the outflow boundary. We performed
123 sensitivity tests using warm bubbles instead of a convergence area to trigger convection, which
124 frequently did not result in the development of deep convection. This is likely because most
125 mid-latitude MCS are baroclinic/synoptically-driven, and not primarily forced by radiational
126 heating.

127 We test 36 current climate condition soundings and 46 future climate soundings at $\Delta x=4\text{ km}$
128 to investigate the development of MCSs. This grid spacing is sufficient to assess if the sounding
129 results in the development of an MCS. A larger number of sounding had to be tested in the future
130 climate because fewer soundings supported the development of organized convection mainly
131 because of a reduction of low-level relative humidity. Based on visual inspection, we select 17
132 cases in each climate that develop an MCS and rank them according to their peak hourly rainfall
133 rate. Members 4 to 14 are selected in both periods and simulated using all six horizontal grid
134 spacings. This is done to increase the robustness of the climate change analysis by excluding
135 atypically strong and weak MCSs. Including high-end extreme events in the analysis would
136 increase the impact of chaotic processes on our climate change assessment and would demand
137 a much larger ensemble of MCSs than we can afford with our available computer resources [29].
138 The 10 current and future soundings that can be used to initialize idealized WRF simulations can
139 be accessed from <https://issues.pangaea.de/browse/PDI-23519>.

140 (c) MCS Processes

141 All analyses are mainly performed on the common grid of the $\Delta x=12\text{ km}$ simulations unless
142 otherwise noted. Conservative remapping [21] was used to ensure the conservation of mass and
143 energy. Comparing the simulations on the same grid helps to assess processes on similar scales.
144 However, this approach averages out small-scale features in the higher resolution simulations that
145 might be important for specific applications (e.g., hail formation or local scale flood assessments).
146 Therefore, the models are also compared on their native grid concerning the characteristics of

147 convective up- and downdrafts and climate change impacts on precipitation. The salient MCS
148 components that are evaluated are shown in Fig. 1.

149 We use an object-based approach for our analyses. This involves thresholding the
150 spatiotemporal data to create a binary field in which objects can be identified. Thereafter, we
151 consider coherent precipitation areas that are connected in space and time as an object – which
152 we refer to as MCS – similar as in our previous work [38,39]. This allows focusing our analysis
153 solely on the MCS by excluding potential secondary convection in the domain. Only objects that
154 do not contact the domain boundaries are considered. Furthermore, for convergence assessments,
155 we only evaluate data three hours after model initialization. At this time, MCSs have reached a
156 mature stage (rainfall area, integrated vertical mass flux) and Δx dependent differences of MCS
157 processes are constant or demonstrate only slow and gradual changes. The only exception are
158 anvil cloud properties, which are evaluated one hour after simulation start since anvil clouds
159 reach the domain boundary typically within the first four hours. This improves the robustness of
160 the analysis but results are similar if anvil clouds properties are evaluated between hour three to
161 four. We suggest the simulations to be "converged" when the differences between simulations
162 at smaller Δx are non-systematic and insignificant, which is the case after three hours. We
163 do not analyse characteristics that are associated with the MCS size (e.g., total precipitation,
164 size of the anvil cloud, cold pool extent) because these characteristics can strongly depend on
165 the initialization of the MCS and vary from real cases that are typically associated with an
166 atmospheric boundary (i.e., synoptic scale forcing).

167 (i) Convective and Stratiform Precipitation

168 To differentiate between the MCS and potential secondary precipitating storms that develop
169 remotely from the MCS, we select the largest contiguous precipitation region with precipitation
170 larger than 0.1 mm h^{-1} . The MCS convective and trailing/detrained stratiform precipitation
171 regions are differentiated by the area with radar 2 km reflectivity $>40 \text{ dBZ}$. This is in accordance
172 with previous radar based observations [1,2].

173 (ii) Draft Geometry and Dynamics

174 We identify drafts within each MCS as 3-dimensional objects of adjacent (horizontally, vertically,
175 and diagonal) grid cells with at least 3 m s^{-1} vertical wind speed for updrafts and -3 m s^{-1}
176 for downdrafts [18]. Only drafts with more than 20 dBZ average reflectivity, below 16 km, and
177 above an area with precipitation of at least 2.5 mm h^{-1} are analyzed to not include clear air
178 vertical motions (e.g., gravity waves) in our analysis. This method is adapted from observational
179 studies using vertical pointing radar for wind profiling [58]. Draft statistics are performed on the
180 native grid to estimate structural convergence of core properties. We randomly selected up to
181 50-cores per output time step (5-minutes) to reduce the computational costs of the analysis for
182 sub-kilometer-scale simulations, which can have several hundred cores.

183 (iii) Cold Pools

184 The spatiotemporal evolution of cold pools is captured with an approach that was used in
185 previous studies [11]. Buoyancy near the surface (b ; m s^{-2}) is calculated following [52]:

$$186 \quad b = \frac{g \cdot (\Theta_p - \bar{\Theta}_p)}{\bar{\Theta}_p} \quad (2.1)$$

187 with g being the gravitational acceleration ($g=9.81 \text{ m s}^{-2}$), Θ_p (K) is the virtual potential
188 temperature, and the overbar indicates a $100 \text{ km} \times 100 \text{ km}$ moving average low-pass filter. Θ_p is
189 defined as:

$$\Theta_p = \Theta \cdot (1 + 0.608 \cdot Q_{vapor} - Q_{cloud} - Q_{rain}) \quad (2.2)$$

where Θ is the potential temperature in Kelvin, and Q_{vapor} , Q_{cloud} , and Q_{rain} are the mass mixing ratios of water vapor, cloud condensate, and rain water in kg kg^{-1} respectively. In accordance to previous studies [5,42], we calculate the cold pool intensity (B ; m s^{-1}) as:

$$B = \sqrt{-2 \int_0^h b dz} \quad (2.3)$$

with buoyancy b (equation 2.1) integrated from the surface to h , which is the height at which b first exceeds -0.005 m s^{-2} . Some of the cold pools are directly connected to downdrafts and can, therefore, reach into the mid-troposphere. To reduce computational resources, we limited the maximum height of cold pools to 3.875 km, which has no significant impact on our results.

(iv) Anvil Cloud Properties

We define the anvil cloud as the contiguous 3D area where the sum of the ice mass mixing ratio (Q_{ice}) and the snow mass mixing ratio (Q_{snow}) is larger than $> 0.1 \text{ g/kg}$. The anvil properties investigated are the average cloud top height and the corresponding cloud top temperature. Cloud top characteristics are analysed between hour three to hour five after model initialization to avoid including statistics when large parts of the anvil are outside the model domain (typically after hour five).

3. Results

In Fig. 2, we show properties of the ten inflow sounding that are used to initialize the idealized current and future climate MCS simulations. Most soundings were derived from MCSs in the first half of JJA. There is a slight shift to earlier sampling dates in the future climate (Fig. 2a). The sounding locations are randomly sampled throughout the central U.S. (Fig. 2b). Note that cumulative CAPE (cCAPE, Fig. 2c) tends to increase in the future soundings at high altitudes. However, below $\sim 7 \text{ km}$ the soundings have similar cCAPE values. The CIN properties (Fig. 2f) do not change significantly between current and future climate scenarios, and the same behavior holds for the relative humidity (RH; Fig. 2d). Constant relative humidity means that the atmospheric precipitable water (PW; Fig. 2g) increases at close to Clausius-Clapeyron rates ($\sim 6.5\%$ per degree warming [8]). Air temperature increases roughly twice as fast at high-levels ($\sim 7^\circ\text{C}$ at 14 km; Fig. 2e) than near the surface ($\sim 3.5^\circ\text{C}$), resulting in a stabilization of the troposphere and an enhanced moistening of upper levels compared to low levels. Ground to low-level wind shear (Fig. 2h) does not change significantly, while median mid-level shear (Fig. 2i) is on average 5 m s^{-1} smaller in future climate soundings. The modeled soundings that we use here are comparable to observed pre-MCS soundings at the U.S. Department of Energy's Atmospheric Radiation Measurement Southern Great Plains site in Oklahoma except for higher low-level RH and lower CIN values in the model soundings [57,58].

(a) Grid Spacing Dependencies Under Current Climate Conditions

In this section we present results addressing our first research question on how MCS components are simulated when using horizontal grid spacings that range from hydrostatic to large-eddy scales. We use an ensemble of 10 idealized MCS simulations to understand the robustness of our results to different MCS environments. All figures in this section feature a representative MCS example to illustrate grid spacing dependent differences followed by ensemble based analysis.

230 (i) Precipitation Characteristics

231 In this section, we assess key precipitation characteristics from the 10-member current climate
 232 MCS ensemble to understand if there are systematic scale-dependent differences. Note that all
 233 ensemble evaluations are performed on a common 12 km grid unless otherwise noted.

234 MCS precipitation features can change significantly contingent on Δx , as shown on the
 235 example of hourly MCS precipitation accumulation in Fig. 3a–g. There is a regime shift in the
 236 spatial structure and location of precipitation when transitioning from hydrostatic ($\Delta x=12$ km) to
 237 non-hydrostatic ($\Delta x \leq 4$ km) grid spacing. Further increasing Δx results in the addition of small-
 238 scale variability and a northward extend of stratiform rainfall but no fundamental changes in
 239 mesoscale structures in the intense precipitation region.

240 Fig. 3h–m shows the ensemble mean and variability of precipitation properties from coarser
 241 Δx simulations compared to their $\Delta x=250$ m counterpart. The location of the MCS track is
 242 remarkably similar (within less than 10 km displacement) for simulations with grid spacings up to
 243 4 km. However, significant track discrepancies occur in the $\Delta x=12$ km simulations (Fig. 3h) with
 244 smaller differences in those without deep convection scheme.

245 Maximum hourly precipitation accumulations suggest a clear regime shift when transferring
 246 non-hydrostatic to hydrostatic simulations with the latter simulations typically showing lower
 247 precipitation intensities and much less accuracy (large ensemble spread; Fig. 3i). Maximum
 248 precipitation is systematically $\sim 20\%$ larger using $\Delta x=4$ km to $\Delta x=1$ km, which is consistent
 249 with previous results [24,46]. A similar behaviour can be seen for mean convective (Fig. 3k) and
 250 stratiform (Fig. 3l) precipitation with the latter showing substantial low biases of $\sim 50\%$ in the
 251 $\Delta x=12$ km simulations due to the lack of a stratiform shield. MCSs movement speed does not
 252 show a strong grid spacing dependence (Fig. 3j).

253 Next we analyse how similar the spatial pattern of the total MCS accumulated precipitation
 254 (hereafter precipitation footprint) are compared to those of the $\Delta x=250$ m simulation. To avoid
 255 penalties from displacement errors we shift the precipitation footprint from the coarser resolution
 256 simulations relative to the footprint of the $\Delta x=250$ m run until the spatial correlation coefficient is
 257 maximized. We see a decrease of correlation coefficients from 0.8 for $\Delta x=500$ m to 0.6 at $\Delta x=2$ km.
 258 $\Delta x=2$ km and $\Delta x=4$ km simulations have similar correlation coefficients while $\Delta x=12$ km show
 259 correlation coefficients around 0.4.

260 In summary, there is a clear regime shift in simulating MCS precipitation characteristics
 261 when transitioning from non-hydrostatic to hydrostatic scales. The latter have significantly
 262 lower skill in capturing the precipitation location, intensity, and spatial patterns simulated by
 263 the $\Delta x=250$ m runs. Additionally, there are clear benefits of not using the Kain-Fritsch deep
 264 convection parameterization at $\Delta x=12$ km in the simulated precipitation characteristics. From our
 265 simulations it is unclear how intermediate grid spacing simulations using $\Delta x=6$ km or $\Delta x=8$ km
 266 would perform, which should be the focus of future studies.

267 (ii) Vertical Mass Flux and Draft Geometry and Dynamics

268 The impact of horizontal model grid spacing on vertical wind speed at mid levels is shown for
 269 one example MCS in Fig. 4a–g. The $\Delta x=250$ m simulation shows high spatial variability with small
 270 but intense vertical up- and downdrafts along the leading edge of the MCS. Additionally, there
 271 are gravity waves propagating ahead of the MCS. These characteristics are qualitatively captured
 272 even in the $\Delta x=4$ km run but the up- and downdraft sizes are larger and less variable. In the
 273 $\Delta x=12$ km runs the MCS collapses into one dominating updraft and gravity waves are largely
 274 absent especially in the simulation with deep convection parameterization.

275 The ensemble average mass flux in the MCSs is overestimated in kilometer-scale models
 276 compared to the $\Delta x=250$ m simulations (Fig. 4h). $\Delta x=1$ km and $\Delta x=2$ km simulations have an
 277 overestimating of more than 33% close to the cloud top while the $\Delta x=4$ km runs overestimates
 278 mass flux by about 20% above 3 km height. The $\Delta x=12$ km simulations have more similar mass
 279 flux statistics compared to the $\Delta x=250$ m than the kilometer-scale simulations, which is likely due
 280 to error cancellation effects (e.g., much larger updrafts with lower vertical wind speeds). Average

281 downward mass flux statistics show similar Δx dependencies compared to upward mass fluxes
 282 (Fig. 4i). Note that the maximum overestimation in the downward mass flux occurs at around
 283 10 km height, which is connected to the maximum overestimation in the upward statistics that
 284 occurs above this level. The enhanced mass flux in kilometer-scale models is likely related to a
 285 underestimation of entrainment and detrainment due to an under-representation of small-scale
 286 turbulence [4,27].

287 The structural convergence of core properties is investigated on the native model grid. Up-
 288 and downdraft characteristics change substantially with Δx . At $\Delta x=12$ km, $\sim 200/150$ km wide
 289 (Fig. 4j,k) and 10/2 km deep up/downdrafts (Fig. 4m,n) are simulated. Updraft width decreases
 290 exponentially with Δx , but start to flatten towards $\Delta x=250$ m, indicating potential convergence
 291 at a higher resolution. This flattening is less pronounced for downdraft widths, meaning that
 292 structural convergence of downdraft width demands smaller Δx than updraft convergence.

293 Updrafts are plume-like (a rising column of warm air) in the $\Delta x=12$ km simulations with an
 294 average depth of 10 km (Fig. 4k), which is consistent with our previous study [58]. Decreasing
 295 Δx makes updraft more thermal-like (rising bubbles of warm air) with a mean depth of 1.25 km
 296 at $\Delta x=250$ m. Mean updraft depth decreases rapidly between $\Delta x=12$ km and $\Delta x=2$ km and
 297 starts to flatten afterwards. In contrast, mean downdraft depth is similar between $\Delta x=12$ km
 298 and $\Delta x=2$ km, starts to decrease from $\Delta x=2$ km to $\Delta x=500$ km, and flattens afterwards (Fig. 4n).
 299 In previous work, we compare a subset of the here used simulations to radar wind-profiler
 300 observations and show that the sub-kilometer scale simulations significantly improve the
 301 representation of draft geometry [58].

302 Mean updraft speed is 6 m s^{-1} in the $\Delta x=12$ km simulations, which is almost twice as fast as in
 303 $\Delta x \leq 250$ m runs (Fig. 4l). The overestimation in the $\Delta x=12$ km simulations of 4.5 m s^{-1} is already
 304 substantially improved in $\Delta x=4$ km runs and starts to converge at $\Delta x \leq 2$ km. Average downdraft
 305 speed is generally less scale sensitive than updrafts speed (Fig. 4o). Here, $\Delta x=12$ km simulations
 306 clearly underestimate the velocity while average downdraft speed does not change significantly
 307 in simulations with $\Delta x \leq 4$ km.

308 (iii) Cold Pool Properties

309 Fig. 5a–g shows the cold pool intensity (see Method section for the definition) of an example MCS
 310 at different horizontal grid spacings. Similar to the precipitation analysis, cold pools also show
 311 a clear displacement when decreasing the Δx from 4 km to 12 km. This is understandable since
 312 these idealized simulations are cold pool driven (e.g., see the development of updrafts along
 313 the leading edge of cold pools in Fig. 1). It is also obvious that the intense part of the cold pool
 314 becomes smaller with increasing Δx and that the location of the intense regions is closer to the
 315 middle of the cold pool in the $\Delta x=12$ km simulations, whereas it is at the leading edge of the cold
 316 pool in the higher resolution runs.

317 The mean cold pool depth is systematically smaller by up to -10% in kilometer-scale
 318 simulations compared to the $\Delta x=250$ m runs (Fig. 5h). Much larger underestimations of -30/-20%
 319 occur in the $\Delta x=12$ km simulations with/without deep convection parameterizations. Maximum
 320 cold-pool intensities are well captured up to $\Delta x=4$ km and are systematically lower in the
 321 $\Delta x=12$ km runs (Fig. 5i). The mean movement speed of cold pools is well captured across all grid
 322 spacings but the ensemble spread is significantly larger in the $\Delta x=12$ km with deep convection
 323 scheme (Fig. 5j). As expected, the movement of the cold pools is similar to the movement of the
 324 precipitation area that was discussed earlier (Fig. 3j).

325 (iv) Anvil Clouds and Hydrometeor Properties

326 Fig. 6a–g shows cloud top temperatures from an example MCS across grid spacings. Similar to
 327 previous analysis, there is a clear change in the spatial structure and average cloud top height
 328 when increasing Δ from 4 km to 12 km. This is also obvious in the ensemble mean cloud top height
 329 statistics (Fig. 6h). Kilometer-scale simulations slightly overestimate the average cloud top height
 330 by up to 200 m while the $\Delta x=12$ km simulations underestimate it by up to 400 m. Furthermore, the

331 ensemble spread increases significantly in the hydrostatic runs with some members having very
332 low cloud top heights. Similar characteristics are seen for maximum cloud top heights that focus
333 on overshooting tops that are associated with the most intense updrafts (Fig. 6i). These results are
334 consistent with the overestimation of vertical mass fluxes and updraft velocities in kilometer-scale
335 simulations (see Section ii).

336 Average cloud water mixing ratios agree well across grid spacings with the exception of higher
337 mixing ratios close to the surface in the $\Delta x \leq 2$ km runs (Supplementary Fig. 2). Average rain water
338 mixing ratios are significantly larger between 2 km and 7 km height for $\Delta x \geq 500$ m. The area with
339 highest graupel mixing ratio around 6 km height is well simulated in simulations with $\Delta x \leq 4$ km
340 and is significantly lower in the $\Delta x \leq 12$ km runs. Simulations with $500 \text{ m} \leq \Delta x \leq 2$ km overestimate
341 graupel close to the surface. Snow mixing ratios in the anvil cloud (10 km to 15 km height)
342 are similar in simulations with $\Delta x \leq 4$ km but significantly larger in the $\Delta x = 12$ km simulation.
343 Ice mixing ratios are small in the Thompson microphysics scheme [51] but are systematically
344 overestimated in all simulations compared to the $\Delta x = 250$ m runs (Supplementary Fig. 2).

345 (b) Grid Spacing Dependence of Climate Change Signals

346 The second question that we asked in the introduction is how model Δx affects the climate change
347 signals of MCS processes, which is addressed in this section. Therefore, we regrid all simulations
348 to the common grid of the $\Delta x = 12$ km simulations and calculate ensemble mean climate change
349 between the 10 member current and 10 member future idealized MCS ensembles. Statistics are
350 calculated for each MCS case first and then averaged over the current and future ensemble using
351 the ensemble spread to calculate statistical significance in future changes.

352 (i) Extreme Precipitation Climate Change Signals

353 Fig. 7a show the 99 percentile (P99; moderately intense precipitation of $\sim 10 \text{ mm}^{-1}$) change of
354 precipitation for accumulation periods ranging from 5-minutes to 3-hours, which represents
355 moderate precipitation intensities. Most obvious is the large increase of P99 precipitation
356 intensities in $\Delta x = 12$ km runs in future climates especially for short accumulation periods. In
357 contrast, simulations with $\Delta x \leq 4$ km do not show any noticeable change.

358 Extreme rainfall rates (99.95 percentile; P99.95) are projected to increase in all simulations
359 and across all accumulation periods (Fig. 7b). Again, much larger increases are simulated in the
360 $\Delta x = 12$ km runs compared to higher resolution models. Not using a deep convection scheme at
361 $\Delta x = 12$ km results in very strong increases across all accumulation periods. The $\Delta x = 4$ km runs
362 produce very similar climate change signals compared to the $\Delta x = 250$ m simulations while the
363 $\Delta x = 2$ km and $\Delta x = 1$ km simulations project systematically $\sim 10\%$ higher extreme intensities for
364 accumulations longer than one hour. This indicates that there are compensating errors in the
365 $\Delta x = 4$ km simulations that enhance the agreement of their climate change projections compared
366 to large eddy simulations and that there is no simple convergence of climate change signals with
367 decreasing grid spacing.

368 Precipitation intensity dependent climate change signals of hourly accumulations also
369 show good agreement between kilometer-scale and sub-kilometre-scale simulations for extreme
370 intensities (Fig. 7c). Hourly precipitation intensification in these simulations is consistent with
371 saturation vapor increases, which is approximately 6.5% per degree warming according to the
372 Clausius-Clapeyron (C-C) relationship [8]. Simulations with $\Delta x = 12$ km, in contrast, result in
373 much higher extreme intensification that can exceed twice the C-C relationship particularly
374 in the simulations without deep convection scheme. Changes in weak and moderate hourly
375 precipitation intensities are more variable than extremes.

376 Repeating the above analysis on the native model grid shows very similar extreme
377 precipitation climate change signals (Supplementary Fig. 3). This confirms that extreme
378 precipitation increases at approximately C-C rates in simulations with grid spacings $\Delta x \leq 4$ km
379 even when localized extremes are considered.

380 (ii) Vertical Mass Flux Climate Change Signals

381 Average upward mass flux increases by $\sim 5\%$ below 7 km height and by more than 33% above
382 12 km in the $\Delta x=250$ m simulations (Fig. 8a). This is consistent with the increase in CAPE at
383 high altitudes in the inflow soundings (Fig. 2c) and generally deeper convection in the future
384 climate (see next section). However, these changes are not significant due to the large variability in
385 average mass flux in the current and future MCS ensemble. These changes are roughly captured
386 in the $\Delta x \leq 4$ km simulations whereas the $\Delta x=12$ km runs simulate a large increase in upward
387 mass flux close to the surface.

388 Also average downward mass flux is increasing in the future $\Delta x=250$ m MCSs with maxima
389 at ~ 5 km and above 16 km height. Simulations using Δx between 500 m and 4 km capture this
390 general pattern while the $\Delta x=12$ km simulations show a large increase in downward mass flux
391 close to the surface instead of the mid troposphere (Fig. 8b).

392 (iii) Cold Pool and Cloud Top Climate Change Signals

393 Cold pools systematically intensify under climate change and deepen by $\sim 5\%$ on average
394 in the $\Delta x=250$ m simulations (Fig. 9a). Cold pool depth changes are similar in kilometer-scale
395 simulations but changes are negative in $\Delta x=12$ km runs that do not use a deep convection scheme.
396 Peak cold pool intensities also intensify by about 8% in the sub-kilometer scale simulations
397 but kilometer-scale simulations show no change - except for the $\Delta x=4$ km runs that show an
398 intensification. The $\Delta x=12$ km simulations show no systematic changes.

399 Average cloud top heights do slightly increase under future conditions in sub-kilometer-
400 scale simulations (Fig. 9c). However, kilometer-scale and the $\Delta x=12$ km simulations without deep
401 convection scheme show a robust deepening of the cloud top by ~ 700 m. Even stronger increases
402 of $\sim 1,300$ m are found in the $\Delta x=12$ km that include the Kain-Fritsch deep convection scheme.
403 A similar but less pronounced sensitivity is present for increases in the peak cloud top height
404 (i.e., overshooting tops; Fig. 9c). Those increase by ~ 550 m in the sub-kilometer and ~ 800 m in the
405 coarser resolution simulations.

406 (iv) Microphysics Climate Change Signals

407 Hydrometeor mixing ratios change significantly under warming due to changes in
408 thermodynamics and dynamics of future MCSs (Fig. 10). There is consensus across grid spacings
409 that cloud water mixing ratios will not change in the lowest 3 km but will increase above up
410 to ~ 10 km height (Fig. 10a). Increases in the mid troposphere are more systematic and intense
411 in kilometer-scale models. A similar upward shift can be seen in rain water mixing ratio, which
412 significantly increases above ~ 9 km and close to the surface (Fig. 10b). This upward shift is mainly
413 due to an increase in the freezing level height and a larger saturation mixing ratio in future
414 climates allowing higher concentrations of liquid particles (partly super-cool droplets) at higher
415 altitude.

416 Large, but non-significant, grid spacing dependencies are shown for graupel mixing ratio
417 showing much larger increases in low and mid levels in the $\Delta x=12$ km simulations than in
418 the higher resolution simulations (Fig. 10c). Particularly the sub-kilometer simulations feature
419 a loss of graupel at lower levels, which is likely driven by enhanced melting [3]. A similar but
420 more significant melting loss at mid-levels can be seen for snow mixing ratio across all grid
421 spacings up to $\Delta x=4$ km (Fig. 10d). Again, the $\Delta x=12$ km runs show different characteristics with
422 larger losses at higher levels and smaller increases in the anvil cloud. Ice mixing ratio show a
423 clear transition from significant decreases below ~ 11 km to increases above with decreases being
424 fairly homogeneous across model resolutions while increases are larger at coarser grid spacings
425 (Fig. 10e).

4. Summary and Conclusion

We perform 10-member ensemble simulations of idealized MCSs under current and end-of-the-century climate conditions at six horizontal grid spacings (Δx) ranging from hydrostatic-scales ($\Delta x=12$ km) to large eddy simulation scales ($\Delta x=250$ m). Several MCS bulk components such as MCS precipitation characteristics, cold pools, drafts, and anvil clouds are compared across model resolutions on a common 12 km grid. The goal is to investigate systematic differences and convergence behaviors in the current climate and the effect of model grid spacing on climate change signals. We decided to focus on mean and extreme aspects of MCSs rather than spatial structures since the latter depends strongly on the initialization of the MCS.

Fig. 11 shows the main differences of MCS features as simulated with hydrostatic, non-hydrostatic, and large eddy grid spacings.

The following conclusions summarize this paper:

- There is a step improvement in simulating MCSs when increasing Δx from hydrostatic (12 km) to non-hydrostatic (≤ 4 km) grid spacings. The $\Delta x=4$ km simulations can reproduce most of the salient MCS features such as track, maximum precipitation, cold pool intensity, and cloud top temperatures from the $\Delta x=250$ m runs within $\pm 20\%$ at 0.02% of their computational costs and 0.4% of their output volume. These results are in agreement with existing MCS literature [7,17,59].
- Minor differences occur between simulations with $\Delta x=4$ km and 1 km when compared on a common 12 km grid. Higher resolution simulations are able to simulate small-scale processes, such as up- and downdraft width and depth, more realistically [58] but this added value has only minor effects on MCS bulk processes.
- A clear deficit of kilometer-scale models is an overestimation of draft velocities and convective mass flux of up to 30% compared to the $\Delta x=250$ m simulations. As a consequence, kilometer-scale models simulate $\sim 20\%$ higher peak rainfall rates and higher and cooler cloud tops. This is likely related to an underestimation of entrainment in kilometer-scale models due to under-resolved turbulent processes [4,27] and a misrepresentation of non-hydrostatic effects [59].
- Recent studies show some benefits in not using deep convection schemes for models with $\Delta x > 10$ km [56]. We confirm these results and show clear advantages in the $\Delta x=12$ km simulations without deep convection schemes compared to the ones with deep convection schemes under current climate conditions (although large differences to the $\Delta x \leq 4$ km simulations still exist). The benefits of not using a deep convection scheme will likely decrease with increasing Δx and key deficiencies (i.e., potential build up of large buoyancy) will start to dominate. Care should be taken since the absence of a deep convection scheme at $\Delta x=12$ km results in much larger increases in vertical mass fluxes and extreme precipitation under future climate conditions.
- Most important for climate modeling is that climate change signals in kilometer-scale simulations agree much better with $\Delta x=250$ m simulations than those from $\Delta x=12$ km runs. However, important differences such as a significant overestimation of extreme rainfall rates in 1 km and 2 km simulations remain, whereas the better agreement in 4 km simulations is likely due to compensating errors. The nature of these compensating errors and the development of scale aware parameterization schemes to mitigate systematic deficiencies in kilometer-scale models should be the focus of future research.

The future MCS environmental conditions are based on simulations that use the pseudo global warming approach assuming that synoptic-scale weather patterns do not change systematically under global warming. We believe that this assumption does not change the main conclusions of this study since it is plausible that future intense MCSs will develop in similar environmental conditions as in the current climate (i.e., moderate wind shear and CAPE, high column average relative humidity, moderate to low CIN). The main differences are an increase in precipitable water, CAPE, and atmospheric stratification, which are captured in the PGW approach [25]. The

477 PGW approach might provide less reliable results for changes in MCS frequencies and shifts in
478 their seasonality, which are not the focus in this study.

479 A caveat of this study is the small sample size (10-current and future MCSs) complicates
480 a robust assessment of climate change effects. Furthermore, results using more realistic MCS
481 simulations might differ from idealized results since MCSs in the U.S. frequently develop along
482 atmospheric boundaries (e.g., fronts, drylines) that affect the organization and evolution of
483 MCSs [16]. Additionally, land-surface heterogeneities can affect the initiation and development
484 of convection [41]. Both of these effects might reduce the sensitivity of MCSs to horizontal grid
485 spacing since these features or heterogeneities provide external forcing that can be captured
486 in kilometer-scale models. We also neglected the impact of radiation and planetary boundary
487 layer effects in our idealized simulations. These effects are likely better represented at LES scales
488 and might increase the sensitivity to horizontal grid spacing. Future research will address these
489 open questions by simulating observed MCSs in the U.S. Southern Great Plains and the Amazon
490 basin. Better understanding the impacts of environmental conditions and model resolution on
491 simulating MCSs is important since the frontier of global-atmospheric modeling has reached
492 kilometer scales [43,49].

493 **Data Accessibility.** All scientific code that was used in this study can be accessed through GitHub [36].
494 The WRF modeling system is open source and is available for download from [https://github.com/
495 wrf-model/WRF](https://github.com/wrf-model/WRF). The sounding data that is used to initialize the idealized MCS simulations are available
496 from <https://issues.pangaea.de/browse/PDI-23519> [35]. The complete ensemble simulation dataset has a
497 data volume of 39 TB and can be accessed by request from the corresponding author.

498 **Authors' Contributions.** Andreas F. Prein has designed the experiments, performed the simulations and
499 analyses. Roy M. Rasmussen, Die Wang, and Scott E. Giangrande contributed to the analyses and the
500 interpretation of results. All authors contributed to the writing of this manuscript.

515 5. Figures & Tables

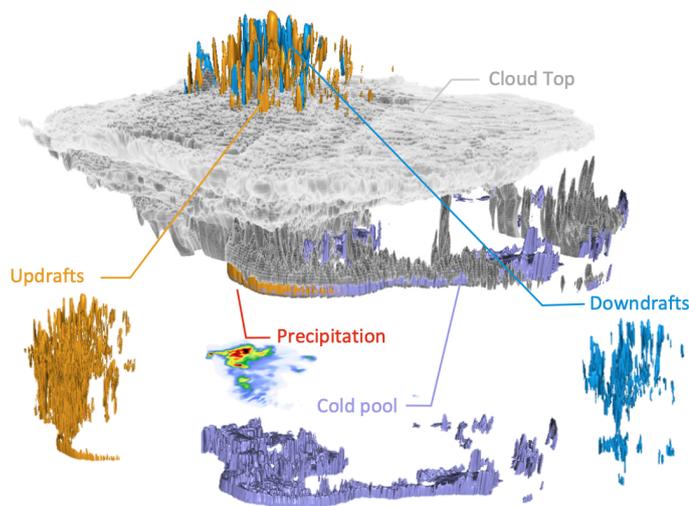

Figure 1. Volume rendering of an example $\Delta x=250$ m MCS cloud field and key MCS components. The vertical extent of the MCS is stretched by a factor of 10.

Table 1. Setup of model simulations. N_x and N_y denote the grid cells in the longitude and latitude direction. All simulations use the Thompson microphysics scheme [51], the Eta surface layer scheme [20], and have 95 vertical levels with 250 m equal distance.

| | large eddy | | kilometer-scale | | | hydrostatic | |
|----------------|------------|-----------|-----------------|---------|---------|-------------|---------|
| Δx | 250 m | 500 m | 1 km | 2 km | 4 km | 12 km | 12 km C |
| N_x/N_y | 2495/2495 | 1247/1247 | 623/623 | 311/311 | 155/155 | 51/51 | 51/51 |
| Δt [s] | 1 | 2 | 4 | 4 | 6 | 10 | 10 |

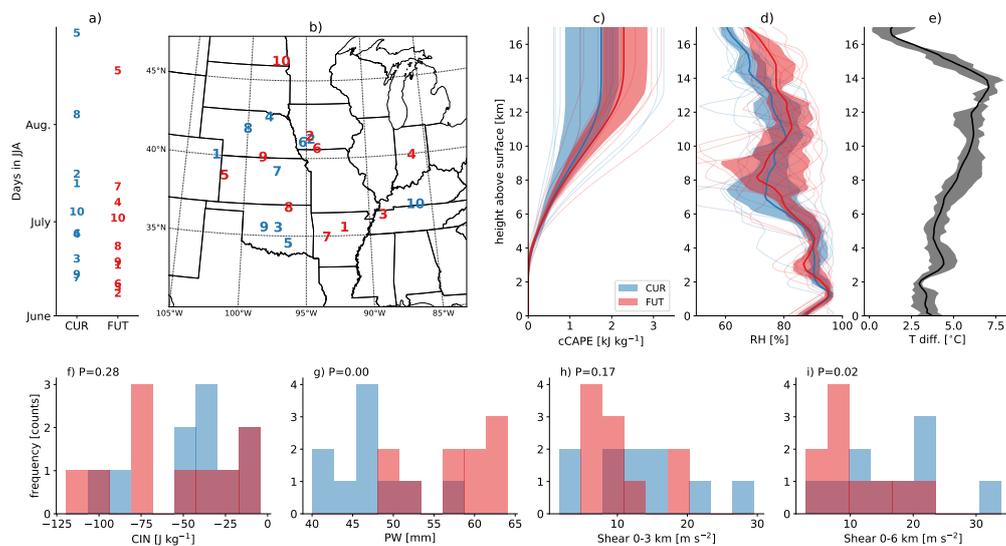

Figure 2. Date (a), location (b), and characteristics (c–i) of current (blue) and future climate (red) MCS inflow soundings that are used to initialize idealized simulations. Thin lines show the cumulative convective available potential energy (cCAPE; c) and relative humidity (RH; d) of individual soundings, thick lines show the ensemble mean, and contours show the ensemble interquartile spread. We show the mean air temperature difference between future and current climate soundings (Tdiff.; e) as a black bold line and the interquartile range as a grey contour. Convective inhibition (CIN; f), precipitable water (PW; g), bulk wind shear between the surface to 3 km (h) and 6 km height (i) are shown in histograms. The significance of differences between the future and current inflow soundings is indicated by the two-sided p-values of a Mann-Whitney rank test (P; f–i).

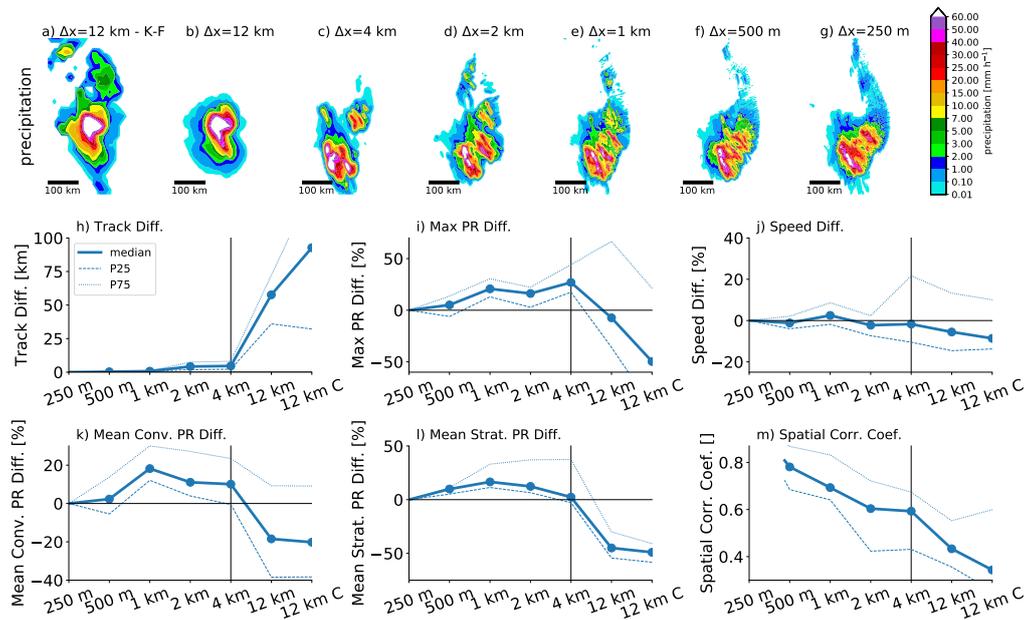

Figure 3. Hourly precipitation accumulation (4:40 to 5:40 after simulation start) of an example MCS case under current climate conditions showing the sensitivity to the model grid spacing from $\Delta x = 12$ km (left) to $\Delta x = 250$ m (right) (a–g). Relative differences in MCS track distance (h), peak precipitation (i), movement speed (j), mean convective (k), and mean stratiform precipitation intensity (l) between current climate MCSs compared to their $\Delta x = 250$ m counterpart. Five-minute model output from mature MCSs (3-hours after initiation and before they reach the domain boundary) are considered. (m) Spatial correlation coefficient of the MCS total precipitation (accumulated over hour three to seven) between coarser simulations and their $\Delta x = 250$ m counterpart. Correlation coefficients are maximized by shifting the precipitation patterns to reduce penalties due to spatial displacements. (h–m) Thick lines show the ensemble median, dashed lines the 25 percentile, and dotted lines the 75 percentile.

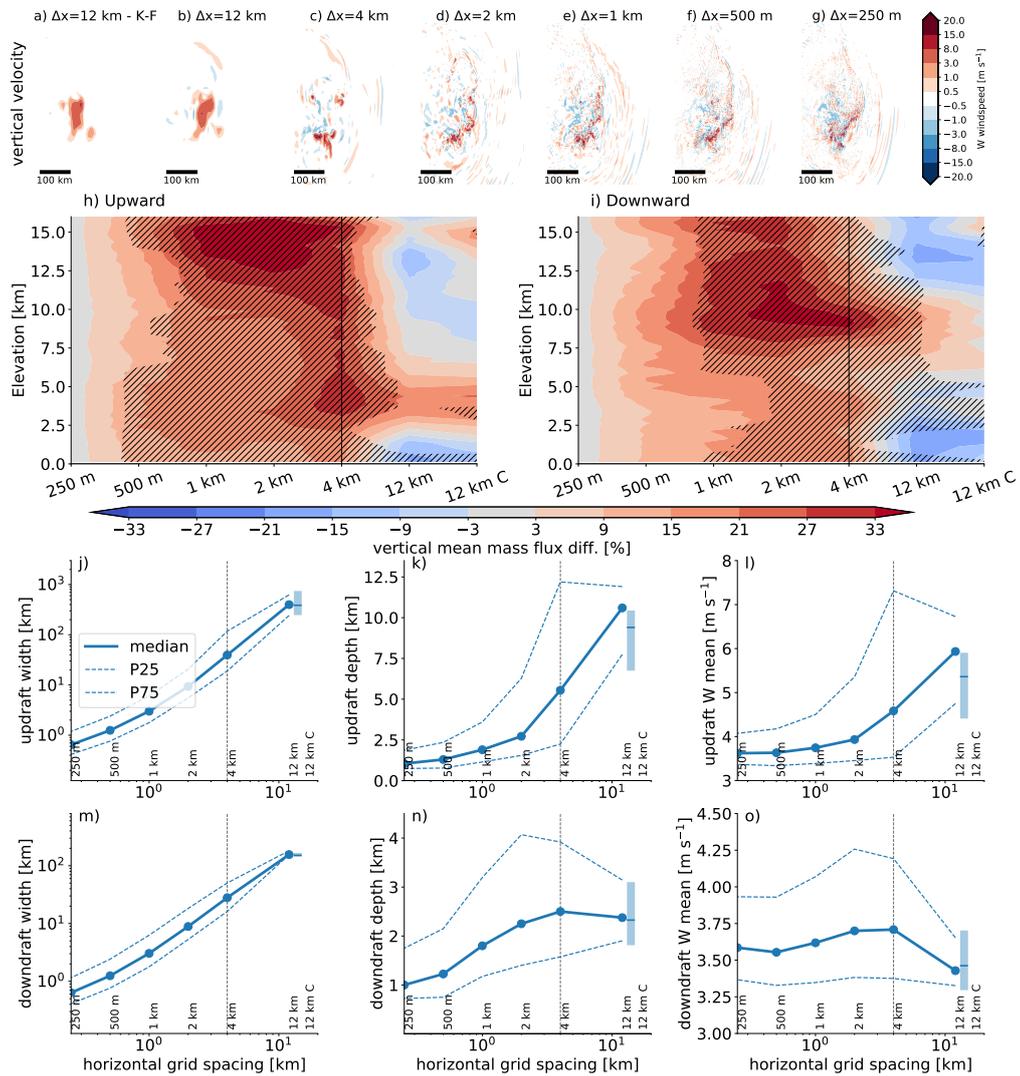

Figure 4. MCS up- and downdraft characteristics dependence on horizontal grid spacing. (a–g) Vertical velocity at 5 km height above surface for the same MCS case as in Fig. 3a–g 4 hours and 40 minutes after simulation start. Accumulated current climate MCS wide upward (h) and downward (i) mass flux differences relative to the $\Delta x = 250$ m simulation based on 5-minute output between hour-3 to hour-7 after simulation start. Up- (j and l) and downdraft (m and o) width (j and m), depth (k and n), and mean velocity dependence on model horizontal grid spacing in current climate MCSs. Thick lines show the ensemble median and dashed/dotted lines the 25/75 percentile. Box whisker plots show results from the $\Delta x = 12$ km simulations with deep convection parameterization. This analysis is performed on the native model grid.

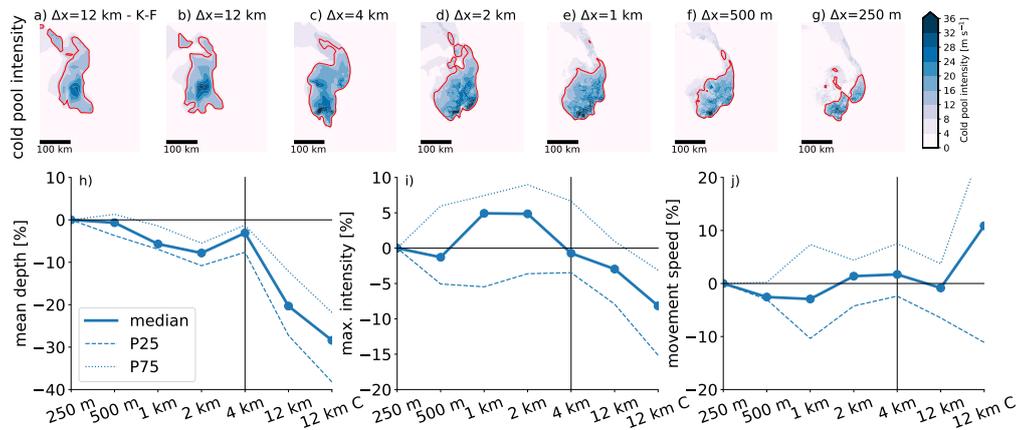

Figure 5. MCS cold pool characteristics dependence on horizontal grid spacing. (a–g) Cold pool intensity for the same MCS case as in Fig. 3a–g 4 hours and 40 minutes after simulation start. The red contour line shows the part of the coldpool that was used for the analysis in (h–j). Average cold pool depth (h), maximum intensity (i), and movement speed (j) differences relative to the $\Delta x=250$ m simulations. Thick lines in h–j show ensemble median differences and dashed/dotted contours show the 25/75 percentile base on 5-minute model.

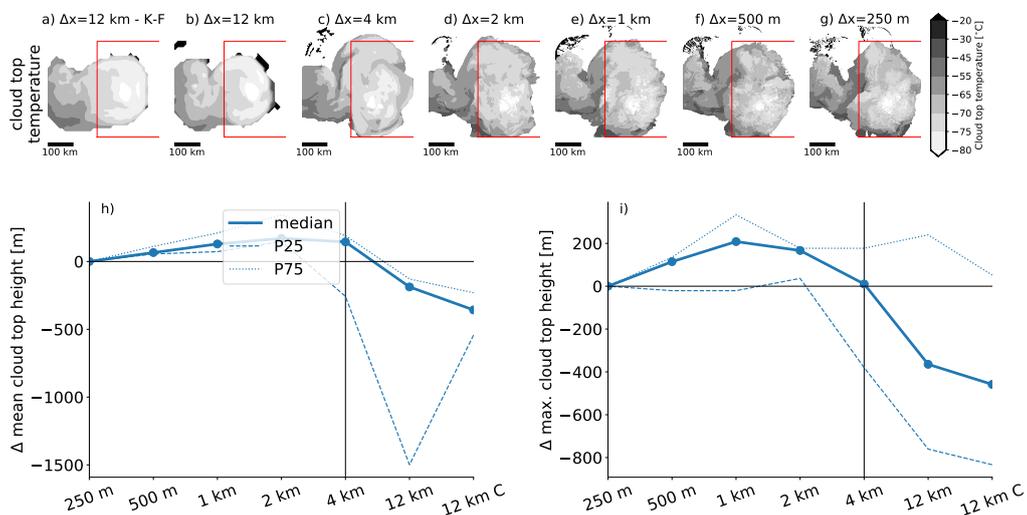

Figure 6. (a–g) Cloud top temperatures for the same MCS case as in Fig. 3a–g 4 hours and 40 minutes after simulation start. The red box shows the area of the MCS that is shown in Fig. 3–5a–g. Average (h) and maximum (i) cloud top height differences relative to the $\Delta x=250$ m simulations. Thick lines in h,i show ensemble median differences and dashed/dotted contours show the 25/75 percentile base on 5-minute model data one hour after simulation start.

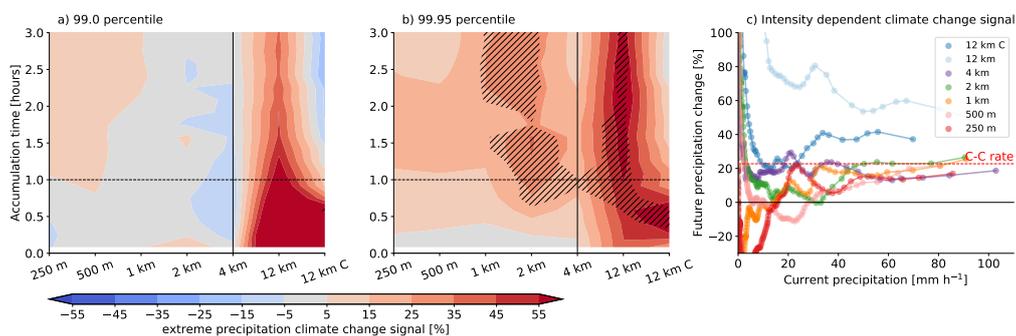

Figure 7. Extreme precipitation climate change signal dependence on horizontal grid spacing and accumulation period for the ensemble mean of 99 (a) and 99.95 (b) percentile values (including zero precipitation). Hatched areas show significant changes in the ensemble mean according to the Mann-Whitney test ($\alpha=0.1$). (c) Average relative climate change signal dependent on hourly precipitation intensity based on the ensemble mean hourly MCS precipitation during the hour with peak precipitation (including zero precipitation).

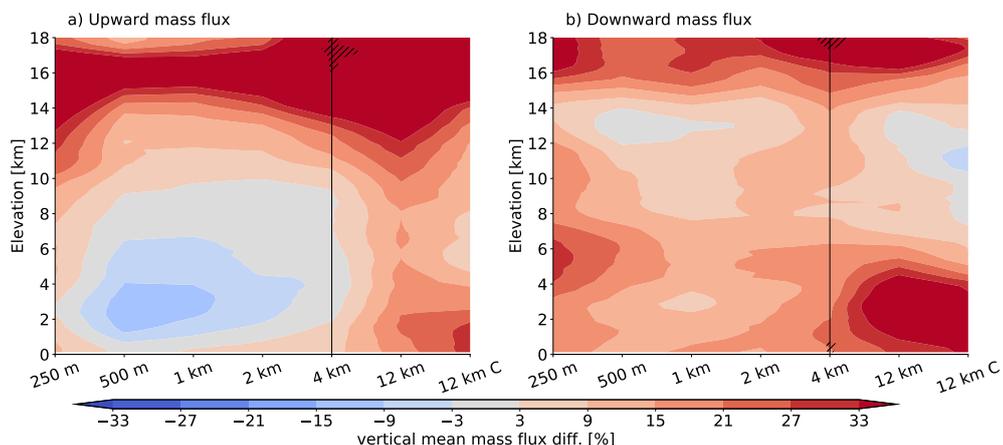

Figure 8. Ensemble mean MCS average up- (a) and down-draft (b) mass flux climate change signal dependence on horizontal grid spacing and height above surface. Hatched areas show significant changes in the ensemble mean according to the Mann-Whitney test ($\alpha=0.1$).

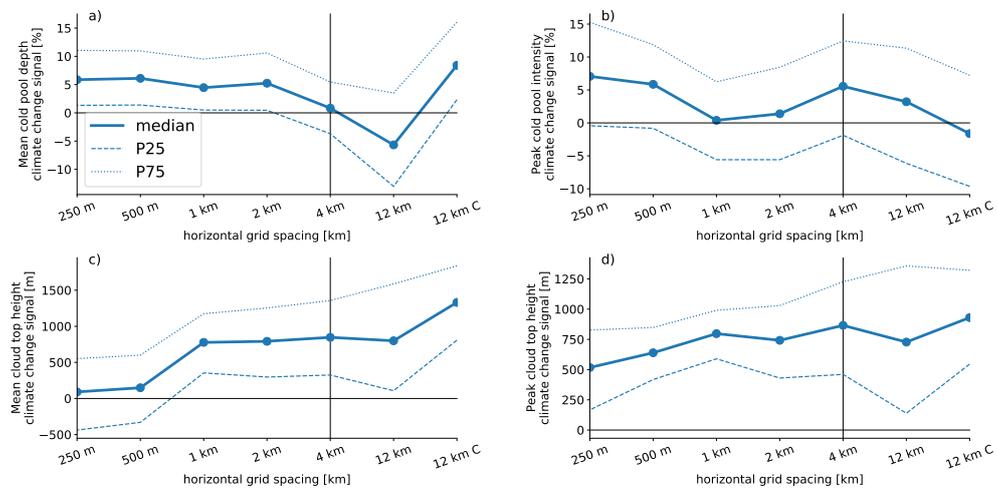

Figure 9. Ensemble climate change signals of mean cold pool depth (a), peak cold pool intensity (b), mean cloud top height (c), and maximum cloud top height (b) depended on horizontal grid spacing. The thick lines show the median and the thin dashed/dotted lines the 25/75 percentile spread of a 1000 member bootstrap sample with replacement.

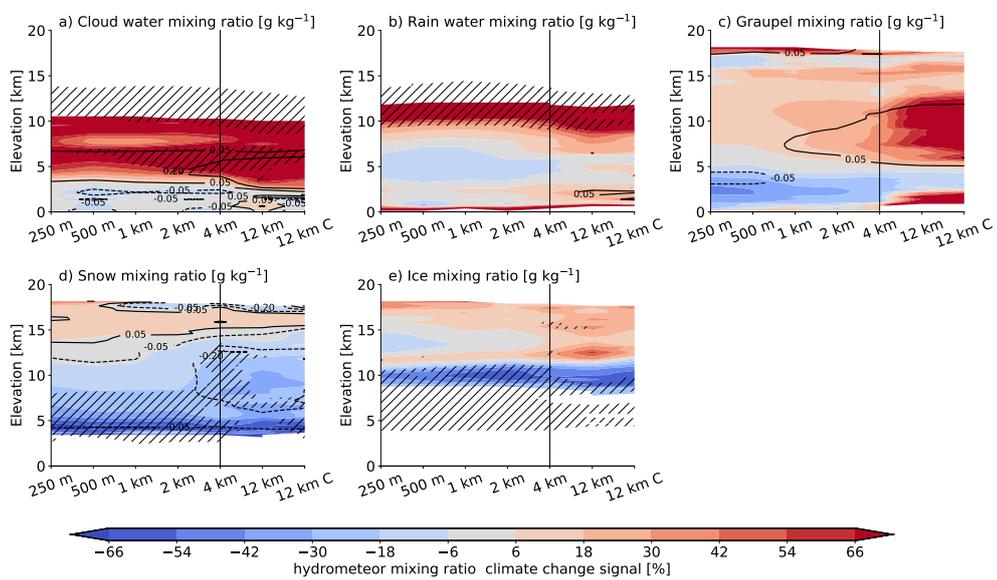

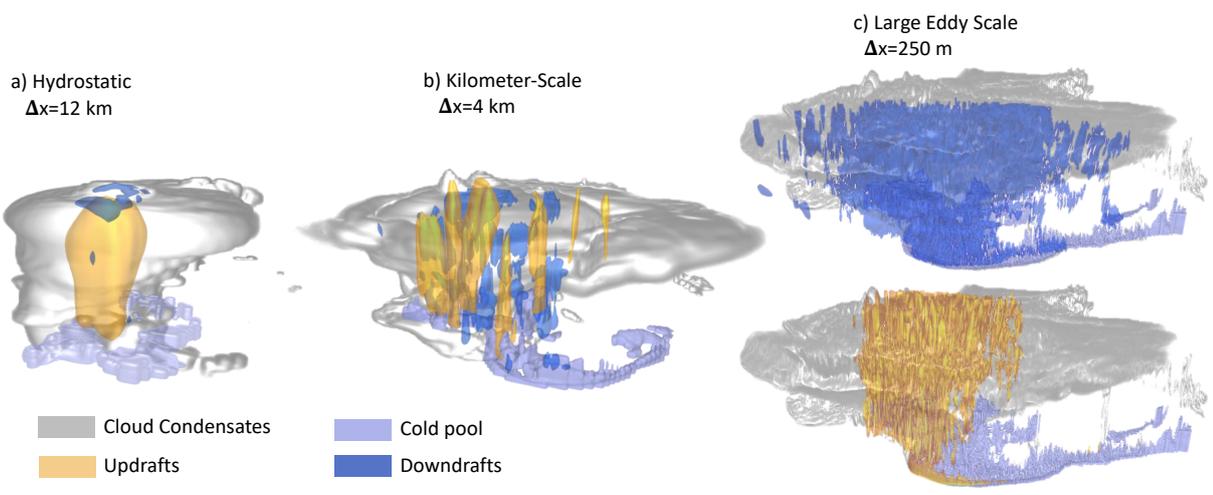

Figure 10. Ensemble mean hydrometeor mixing ratio climate change signals. Shown are results for in-cloud (particle mixing ratio $> 0.1 \text{ g kg}^{-1}$) mixing ratios for horizontal cloud fields larger than 7.200 km^2 for cloud water (a), rain (b), graupel (c), snow (d), and ice (e) for hour one to seven after simulation start. Hatching shows significant differences ($\alpha=0.05$) and contour lines show absolute differences (in g kg^{-1}).

| MCS Feature | Hydrostatic $\Delta x = 12 \text{ km}$ | Kilometer-Scale $1 \text{ km} \leq \Delta x \leq 4 \text{ km}$ | Large Eddy Scale $\Delta x = 250 \text{ M}$ |
|----------------------|---|---|--|
| Precipitation | Too localized; 20% -to 50% too weak | Hourly heavy precipitation patterns have converged; Average and peak precipitation is ~20% too intense | Patterns and peak intensities have converged; Stratiform precipitation rates have not converged |
| Cold Pools | ~20% too weak | ~5% too weak on average; Maxima well captured | Structures and intensities have converged |
| Updrafts | Plume-like (rising column of air) One draft that is very wide, deep, and 100% too intense on average | Thermal-like (rising bubbles of air); Few thermals that are too wide, too deep, and 10% to 30% too intense | Many thermals with converged average depth and speed; Updraft width has not converged |
| Downdrafts | Very few drafts that are 130% too deep, too wide, and 12% too weak | Few drafts that are too wide and 60% to 130% too deep; Average speed has converged | Many drafts with not converged average width and depth |
| Cloud Tops | 1 °C too warm and ~300 m too low; Large parts of the anvil are missing | 1 °C too cold and up to ~200 m too high; Average extend has converged | Cloud top temperature and height have not converged |

Figure 11. MCS features as simulated with hydrostatic (a, $\Delta x=12 \text{ km}$), kilometer-scale (b, $\Delta x=4 \text{ km}$), and large eddy scale (c, $\Delta x=250 \text{ m}$) horizontal grid spacing based on a representative example MCS. Shown are the cloud condensates (grey shading), cold pools (violet; -0.005 m s^{-2}), updrafts (orange; $>3 \text{ m s}^{-1}$), and downdrafts (blue; $<-1.5 \text{ m s}^{-1}$). The vertical axis is stretched by a factor of 10. The table summarizes the main differences between features simulated by hydrostatic and kilometer-scale runs compared to those in the large eddy simulations.
