

Abstract

Tropical deep convective clouds are important drivers of large-scale atmospheric circulation representing the main vertical transport pathway through the depth of the troposphere for heat, momentum, water, and chemical species. The strength and depth of this transport are impacted by the convective updraft size and intensity that are driven by buoyancy, dynamical forcing, and mixing of environmental air, i.e., entrainment. In this study, we identify tropical deep convective systems with well-defined forward anvils using Atmospheric Radiation Measurement (ARM) ground-based profiling radars, at three ARM fixed-sites in the Tropical Western Pacific (TWP; i.e., Manus, Nauru, Darwin) and three ARM Mobile Facility deployments in Niamey, Niger; Gan Island, Maldives; and Manacapuru, Brazil. We use the difference between the level of neutral buoyancy (LNB) and the level of maximum detrainment (LMD) as a proxy for the effective bulk convective entrainment (ε_{proxy}). The LNB, the theoretical height that a parcel raised above the level of free convection would reach with no mixing, is calculated based on pre-convection radiosonde measurements using parcel theory. The LMD is the height of the maximum reflectivity observed in forward anvil clouds by profiling radars.

Deep convective systems over the TWP show higher LNBs that extend to 16.3 km on average and larger ε_{proxy} (median LNB minus LMD up to 6.5 km) compared to their continental counterparts in the Amazon and West Africa. Oceanic conditions show larger convective available potential energy (CAPE) coupled with higher moisture at low levels which favors larger ε_{proxy} . In contrast, continental cases initiate and develop under high convective inhibition, steeper environmental lapse rate, and high wind shear conditions, which show smaller offset between LNB and LMD. Deep convective cases that promote significant cold pools at the surface experience less ε_{proxy} . Using a Random Forest regression algorithm, CAPE is associated with the highest feature importance score for predicting convective ε_{proxy} , followed by low-level relative humidity. For continental cases, the low-level wind shear also indicates higher importance.

1 Introduction

A common feature of tropical regions, deep convective clouds help regulate the global energy and water cycles (e.g., Fritsch et al., 1986; R. A. Houze, 2004; R. A. Houze Jr., 2018), and are the primary vehicle to transport heat, moisture, and momentum from the boundary layer upward to the dry upper troposphere and lower stratosphere through convective updrafts (e.g., Bretherton & Smolarkiewicz, 1989; de Rooy & Pier Siebesma, 2010). As cumulus convection deepens, an important aspect of its development is the horizontal outflow that preferentially occurs in the upper troposphere and is controlled by the strength of the convective updrafts. This outflow from the convective cores is called dynamical detrainment (e.g., Raga et al., 1990; Dawe & Austin, 2011), and these detrainment processes help form widespread stratiform and long-lasting anvil clouds that influence the net radiative forcing of the atmosphere (e.g., Hartmann et al., 2001; Jensen et al., 2002; Jensen & Del Genio, 2003; Stephens, 2005). Complementing these mass detrainment processes are cloud entrainment processes that govern the updraft size and intensity, and affect the strength and depth of this mass transport (e.g., Stommel, 1947). Moreover, entrainment cools the ascending convective parcels and decreases the liquid water content in active convection by mixing drier, cooler environmental air into moist updraft regions. Thus, entrainment processes result in a dampening of convective buoyancy and a subsequent decrease in the level of maximum detrainment (e.g., Derbyshire et al., 2004; Del Genio & Wu, 2010).

The treatment of the cloud entrainment/detrainment process has been identified as a bottleneck for current global climate model (GCM) representation of deep convection, as well as simulations to cloud-resolving model (CRM) scales (e.g., Kain & Fritsch, 1990; Bretherton et al., 2004; Romps, 2010; Klocke et al., 2011; Kim & Kang, 2012; Del Genio et al., 2012; Stirling & Stratton, 2012; Anber et al., 2019). For instance, a small change to the parameterization of the entrainment rate can introduce a significant shift in the timing or amplitude of the convective diurnal cycle (e.g., Yang & Slingo, 2001; Del Genio & Wu, 2010), thereby altering the large-scale circulation and resulting in significant climate variability (e.g., Tokioka et al., 1988; Maloney & Hartmann, 2001; Sanderson et al., 2008; Hannah & Maloney, 2011). One explanation for the continuing challenge is that observational constraints for model process improvement (or convective parameterization) including cloud entrainment rates, mass flux, and mass detrainment properties for deep and/or tropical cumulus are extremely difficult to obtain. Moreover, convective cloud

80 processes operate across a wide range of spatiotemporal scales, and aircraft in-situ ob-
81 servations are costly, unavailable over remote tropical/oceanic regions, and hazardous
82 in the stronger convective cloud conditions (e.g., Guo et al., 2015). Thus, observational
83 constraints are often restricted to a small subset of convective cloud-types and thermo-
84 dynamic conditions for limited parameterization improvement in the models (e.g., Co-
85 hen, 2000; Mullendore et al., 2005).

86 This study is motivated by the deficiencies in our observational understanding of
87 the bulk entrainment and mass detrainment processes that impact tropical deep convec-
88 tion. We emphasize the mass detrainment aspects of this problem, as it can be argued
89 that current remote-sensing instrumentation are capable of characterizing the heights
90 at which most of the air transported by convective updrafts detrains in convective anvil
91 cloud regions. In this regard, observed detrainment levels are found to be strongly de-
92 pendent on the updraft strength and the conditions in which that deep convection ini-
93 tiates and develops (e.g., Hartmann & Larson, 2002). Furthermore, estimates for the ob-
94 served levels of maximum detrainment (as well as the net detrainment mass flux) are ex-
95 pected to vary significantly with convection type, size, and age (e.g., Barnes et al., 1996;
96 Norgren et al., 2016). Previous studies (e.g., Takahashi & Luo, 2012) have argued that
97 differences in the detrained outflow heights and the level of neutral buoyancy can act as
98 a simple proxy for effective bulk convective entrainment. These concepts have been ap-
99 plied to satellite-based observations to study cloud growth and entrainment for deep con-
100 vective systems in the Tropics (e.g., Takahashi & Luo, 2012; Takahashi et al., 2017), as
101 well as through the use of ground-based precipitation radar measurements applied to case
102 study examples (e.g., Dual-Doppler radar; Mullendore et al., 2013; Carletta et al., 2016).
103 However, this proxy bundles several non-adiabatic terms that impact convective plume
104 buoyancy into a single quantity, due to the lack of observational platform constraints.
105 The buoyancy of the rising air parcel could be affected by several processes other than
106 entrainment, including hydrometeor drag, latent heating during hydrometeor phase changes,
107 and nonhydrostatic pressure effects. Water loading contributes to frictional drag forces,
108 as condensation and precipitation growth processes occur, which decreases the acceler-
109 ation of the rising parcel (e.g., Jorgensen & LeMone, 1989). The significance of this con-
110 tribution to convective vertical velocity remains a topic of debate (Sherwood et al., 2013;
111 Romps & Charn, 2015). In addition, the perturbation pressure field plays a major role

112 in reducing the sharp gradients in vertical velocity near the cloud top (Holton, 1973; Chen
113 & Sun, 2002).

114 For simplicity, we refer to this as an effective bulk entrainment proxy (ε_{proxy}) and
115 apply these ideas to an extensive ground-based archive for cloud observations. We draw
116 from a multi-year, multi-site record available from the U.S. Department of Energy's (DOE)
117 Atmospheric Radiation Measurement (ARM) program that has advanced cloud sampling
118 in remote, tropical regions (e.g., Mather & Voyles, 2013). ARM cloud radar observations
119 are coupled with co-located, routine radiosonde launches to determine the ε_{proxy} for dif-
120 fering tropical environments (i.e., continental, coastal, oceanic). A detailed description
121 of the DOE ARM sites, instruments, measurements, and study methodology are given
122 in Section 2. Section 3 describes the regional variations of thermodynamic conditions for
123 identified deep convective systems. Section 4 explores how environmental parameters are
124 related to the ε_{proxy} in tropical convective clouds, and which explain the most variabil-
125 ity in the ε_{proxy} . We provide a summary of the primary conclusions from this study in
126 Section 5.

127 2 Date and Methods

128 2.1 ARM Sites

129 The ground-based measurement record from multiple U.S. DOE ARM sites (Stokes
130 & Schwartz, 1994; Ackerman & Stokes, 2003; Mather & Voyles, 2013) provides the long-
131 term and high-resolution observations of cloud properties and atmospheric state that form
132 the basis of the analyses presented in this study. Our focus is on six ARM deployment
133 sites in the Tropics, and includes fixed multi-year deployments and 1-2 year ARM Mo-
134 bile Facility (AMF; Miller et al., 2016) deployments. We plot the locations and additional
135 details for these deployments in Figure 1. Historically, the ARM program operated three
136 fixed sites along the equator in the Tropical Western Pacific Ocean (TWP; Mather et
137 al., 1998; Long et al., 2013, 2016), motivated by the need to sample the migration of the
138 intertropical convergence zone (ITCZ) and the phases of the El Niño-Southern Oscilla-
139 tion (ENSO). The initial TWP site (TWP-C1) was established on Manus Island in Papua
140 New Guinea, in the middle of the tropical warm pool where the environment is influenced
141 by the Madden-Julian oscillation (MJO) and the site experiences persistent cloudiness
142 and rainfall (e.g., McFarlane et al., 2013). The second TWP site (TWP-C2) was located

143 on Nauru Island in the Republic of Nauru, on the eastern edge of the tropical warm pool.
144 This location exhibits strong variability in precipitation characteristics and convective
145 properties, as attributed to ENSO cycles (e.g., Jensen et al., 1998; Porch et al., 2006).
146 A third coastal site (TWP-C3) was in Darwin, Australia, which is dominantly affected
147 by the annual Australian monsoon system (e.g., P. T. May et al., 2012; Giangrande et
148 al., 2014).

149 Three additional tropical datasets were collected during recent AMF campaigns,
150 which include one tropical-oceanic location and two tropical-continental deployments.
151 The earliest continental-tropical site deployment was located in Niamey, Niger (NIM;
152 Miller & Slingo, 2007), with AMF1 operations from January 2006 to January 2007 as
153 part of the African Monsoon Multidisciplinary Analysis campaign (Lebel et al., 2003).
154 This one-year experiment continuously measured the seasonal variations in cloud and
155 radiation properties in Niamey, which are strongly influenced by Saharan desert dust and
156 biomass burning during the dry seasons and frequent deep convective activity after the
157 arrival of the West African Monsoon (e.g., Miller & Slingo, 2007; Slingo et al., 2008; Kol-
158 lias et al., 2009). A second tropical-continental dataset was collected in the central Ama-
159 zon basin near Manacapuru, Brazil (MAO) during the Observations and Modeling of the
160 Green Ocean Amazon 2014-2015 (GoAmazon2014/5) Experiment from January 2014 to
161 November 2015 (Martin et al., 2016). In the Amazonian tropical forest, the synoptic cir-
162 culation patterns change across seasons impacting the convective cloud types and organ-
163 ization, further complicating the aerosol-cloud-precipitation interactions (e.g., Giangrande
164 et al., 2017; Machado et al., 2018; Wang et al., 2018). Finally, a tropical-oceanic deploy-
165 ment of the AMF was on Gan Island, Maldives (GAN; Long, 2010, 2011), during the ARM
166 MJO Investigation Experiment (AMIE-Gan) from October 2011 to March 2012. The GAN
167 site is located in the middle of the Indian Ocean where the convection population and
168 precipitation amount vary significantly according to the phases of the MJO (e.g., Yoneyama
169 et al., 2013).

170 2.2 Measurements

171 The Active Remote Sensing of CLOUDS (ARSCL; Clothiaux et al., 2000; Kollias et
172 al., 2005) value added product (ARM, 1999) is the primary dataset used in this study
173 to identify deep convective clouds and characterize cloud properties. This product merges
174 observations from vertically-pointing millimeter cloud radar, laser ceilometer, micropulse

175 lidar, and microwave radiometer to describe the cloud vertical structure at high resolu-
176 tion (~ 10 s, ~ 24 m). Overall, ground-based cloud radars are capable of sampling the
177 forward anvil clouds of deep convection when there is limited attenuation in rain and/or
178 few underlying clouds (e.g., Kollias et al., 2007). At different locations, ARM cloud radars
179 operate at different frequencies, with 95 GHz W-band ARM Cloud Radar (WACR; Widener
180 & Mead, 2004; Giangrande et al., 2012) at NIM and MAO, and 35 GHz Ka-band ARM
181 Zenith Radar (KAZR or MMCR [Millimeter-wavelength Cloud Radar]; Kollias et al., 2007;
182 Widener et al., 2012) at GAN and the three TWP sites. Additional details on radar type
183 and location are summarized in Table 1. Although these different radars and operating
184 wavelengths carried different beamwidths, sensitivities to clouds, and slight changes in
185 small anvil/ice particle scattering and/or potential for gaseous attenuation or attenu-
186 ation in rain, these differences do not significantly impact the determination of the bulk
187 anvil properties of interest for this study.

188 The surface atmospheric conditions are provided by a collocated standard Surface
189 Meteorological System (MET; ARM, 2013) at each ARM site. These sensors record 1-
190 min observations of temperature, specific humidity, and rainfall rate. Depending upon
191 the geographical area and local conditions, different types of surface sensors were deployed
192 to measure these surface quantities. Detailed information on these sensors and additional
193 surface variables measured at each ARM site can be found in Ritsche (2011) and Table
194 1. Thermodynamic profiling is available from ARM radiosondes routinely launched 1 to
195 6 times per day according to the site and field campaign designations (ARM, 2019). The
196 Vaisala RS-92 radiosondes have been used as part of regular operations for ARM AMF
197 deployments, and became a standard at all of the ARM sites since 2005 (Holdridge et
198 al., 2011; Jensen et al., 2015). For the three TWP sites that have the longest records in
199 the program, three generations of radiosondes (i.e., RS-80, RS-90, and RS-92) have been
200 used and replaced since the beginning of the deployments (Holdridge et al., 2011, Ta-
201 ble 1). For the planetary boundary layer (PBL) height, we use the estimates based on
202 a bulk Richardson number method developed in Seibert et al. (2000) using the radiosonde
203 measurements (Sivaraman et al., 2013; ARM, 2014).

2.3 Methodology

2.3.1 Case Selection

Deep convective events were selected based on time-height profiles of ARSCL best-estimate reflectivity (e.g., Figure 2). Selected events are required to have a cloud-top (radar echo top) height greater than 10 km, with an extensive forward anvil cloud, which is defined as extended cloud at the top and leading edge of a deep convective cloud with continuing observations from ground-based profiling radar for a minimum of 30 minutes and having a cloud base above 5 km. These criteria are similar to previous satellite-based definitions in studies by Takahashi and Luo (2012) and Takahashi et al. (2017). We limited our samples to the convective events that have radiosondes launched within 6 hrs prior to the convective updrafts passing over the sites. Based on this visual inspection, we identify 320 tropical deep convection events (listed in Appendix Table A1) that meet these criteria (i.e., 11 for GAN, 23 for NIM, 36 for MAO, 173 for TWP-C1, 16 for TWP-C2, 61 for TWP-C3). We plot an example of one event from 6 December, 2005 at the TWP-C1 site in Figure 2, with a forward anvil cloud indicated by the black box. Note that while the presence of a pronounced anvil feature intrinsically implies that we only consider deeper convective events at mature to later lifecycle stages, we recognize that the characteristics of convection (e.g., updraft intensity, cold pool properties, detrainment height) can also vary significantly from updraft-dominant early mature to downdraft-dominant later mature stages (e.g., Mullendore et al., 2013; Feng et al., 2018).

2.3.2 Level of Neutral Buoyancy

Pre-convection radiosondes are used to estimate thermodynamic variables following parcel theory with different assumptions, considering both irreversible pseudo-adiabatic and reversible moist adiabatic ascents. Ice phase is considered in the parcel model, which provides an additional source of positive buoyancy above the melting level from latent heat released during freezing. When assuming the air parcel experiences undiluted ascent in a pseudo-adiabatic process, we neglect hydrometeor loading. An unsaturated air parcel lifted from the surface or boundary layer will eventually reach a level where it becomes saturated due to dry adiabatic cooling (i.e., the lifting condensation level, LCL). As this air parcel is further lifted following the moist adiabatic lapse rate, it will rise to the level of free convection (LFC) where it becomes positively buoyant and accelerates

235 upward. When the buoyancy decreases to zero again during its ascent, this parcel reaches
 236 the level of neutral buoyancy (LNB). As the LNB calculation is highly sensitive to the
 237 choice of the initial parcel, we performed our tests for a surface-based parcel, the most
 238 unstable parcel, and the mixed-layer parcel. The surface-based parcel is defined as the
 239 parcel at the lowest sounding data level; the most unstable parcel is defined as the par-
 240 cel that has the greatest virtual temperature in the lowest 700 mb above surface; the mixing-
 241 layer parcel is defined as the parcel with properties of the mean of the boundary layer.
 242 Choosing the most unstable parcel elevates the LNB (LNB_{mu}) by 0.6 km on average com-
 243 pared to the surface-based LNB (LNB_{sfc} , Figure 3a), which is consistent with findings
 244 in Mullendore et al. (2013). When considering the mixed-layer parcel (in order to elim-
 245 inate the enhanced heating at the surface), the mean LNB lowers dramatically (by 1.6
 246 km compared to LNB_{mu}) as the calculation is based on the mean air parcel condition
 247 (e.g., temperature and humidity) below the PBL height. In order to investigate the lim-
 248 itation of pseudo-adiabatic assumption and the role of hydrometeor loading on parcel
 249 buoyancy, we incorporate reversible moist adiabatic ascent in the parcel model. Assum-
 250 ing reversible moist adiabatic ascent reduces buoyancy and lowers the mean LNB (LNB_{rev})
 251 by about 2.5 km compared to the irreversible pseudo-adiabatic ascent (LNB_{mu} , Figure
 252 3a).

2.3.3 *Level of Maximum Detrainment*

254 In reality, the convective air parcel rarely rises to the LNB before detraining from
 255 the convective cores. The buoyancy of the rising air parcel will be affected by entrain-
 256 ment, hydrometeor drag, latent heating during hydrometeor phase changes, and nonhy-
 257 drostatic pressure effects. Through the combined influences of these processes, the level
 258 of maximum detrainment (LMD), as the altitude where most of the air mass and ice par-
 259 ticles detrain horizontally after convective parcels decelerate, will be lower than the es-
 260 timated LNB.

261 Following Mullendore et al. (2009) and Takahashi et al. (2017), the LMD is deter-
 262 mined by the height of the maximum radar reflectivity within the forward anvil cloud.
 263 We calculate the bulk entrainment rate proxy, ε_{proxy} (e.g., Takahashi & Luo, 2012) as
 264 the difference between the idealized LNB and observed LMD, recalling that this proxy
 265 encompasses the effects of entrainment and other processes that contribute to the de-
 266 celeration of the rising convective parcel. To avoid the noisiness in the measurements,

our first step is to average the reflectivity field within the forward anvil clouds at each height level, then locate the maximum mean reflectivity in altitude (LMD_{mean}). As a sensitivity test for this approach, we also consider the height of the maximum reflectivity in the anvil without performing the averaging step (LMD_{max}). The probability density functions of LMDs are plotted in Figure 3a as compared to the LNBs estimated for all events. The distributions of LMD_{mean} and LMD_{max} are nearly identical (mean ~ 10.5 km) and lower than the corresponding LNB_{mu} with an average offset of ~ 5 km, as shown in Figure 3b. These differences are comparable to previous findings based on satellite observations and parcel model calculations with the irreversible pseudo-adiabatic assumption (offset ~ 4 km, Takahashi et al., 2017). This 1-km difference between satellite and ground-based methods is potentially attributed to differences in vertical resolution and attenuation between the CloudSat nadir-pointing W-band (94 GHz) Cloud Profiling Radar (Tanelli et al., 2008) and ARM ground-based profiling radars (KAZR, MMCR, and WACR; Kollias et al., 2007; Widener et al., 2012), as well as the different radar sensitivity limits when sampling anvil ice particles (e.g., higher ground-radar sensitivity). Another contributing factor is that cumulative ARM dataset properties are dominated by TWP oceanic cases that should promote relatively higher LNBs compared to other tropical sites.

Note that, the irreversible pseudo-adiabatic and reversible moist adiabatic ascents are both idealized extremes, and the real LNB falls somewhere in between. This partially explains the negative ε_{proxy} values in Figure 3b, where the LNBs are being underestimated for the cases that have hydrometeors fall out of the parcel. When using mixed-layer parcels, negative ε_{proxy} values could also be expected, since we assume the entire boundary layer is well mixed prior to convection, which represents another extreme case. In addition, the errors in the PBL height retrievals, the representativeness of the selected soundings for the local condition, and the limitations in the parcel theory such as in realistically describing the size of the initial parcel and the lifting mechanisms add additional uncertainties to the ε_{proxy} estimates.

2.3.4 Candidate Environmental Parameters

We consider a subset of candidate environmental parameters that are anticipated to be important for determining entrainment, updraft strength and regulating the overall convection evolution (e.g., Weisman & Klemp, 1984; Lucas et al., 1994b; McCaul &

299 Weisman, 2001; Kirkpatrick et al., 2009; Wang et al., 2019). Bulk environmental param-
 300 eters such as convective available potential energy (CAPE) and vertical wind shear of
 301 the horizontal winds are important drivers of the convective lifecycle and are often com-
 302 ponents of convective parameterization schemes (e.g., Zhang & McFarlane, 1995; Gre-
 303 gory, 2001). Additional variables such as the convective inhibition (CIN), LFC, and the
 304 vertical distribution of cloud parcel buoyancy also have an important impact on the con-
 305 vective properties. In this study, a total of nine environmental quantities of interest are
 306 chosen as candidates for explaining the variability in the ε_{proxy} .

307 The CAPE, a measure of the work done by a parcel ascending from the LFC to the
 308 LNB, is a critical control in understanding deep convective clouds. We calculate CAPE
 309 under both irreversible pseudo-adiabatic ascent (for three different initial parcels, includ-
 310 ing the surface parcel, the most unstable parcel, and the mixed layer parcel, as $CAPE_{sfc}$,
 311 MUCAPE, and $CAPE_{mix}$, respectively) and reversible moist adiabatic ascent (for the
 312 most unstable parcel, as $CAPE_{rev}$). The mean $CAPE_{sfc}$ (2357 J/kg), $CAPE_{mix}$ (1192
 313 J/kg), and $CAPE_{rev}$ (985 J/kg) are much lower than the mean MUCAPE (2820 J/kg),
 314 demonstrating how this calculation of CAPE is sensitive to the thermodynamic charac-
 315 teristics of the initial parcel and the microphysical assumptions in the parcel model. To
 316 represent the shape of the buoyancy profile, we also calculate low-level CAPE (LCAPE)
 317 following Blanchard (1998) by integrating buoyancy through 4 km above the LFC. In
 318 addition, we also consider other environmental parameters of interest, such as the en-
 319 vironmental temperature lapse rates (ELRs, 0-3 km and 3-6 km), the low-level mean rel-
 320 ative humidity (RH) from surface to 5 km, and the low-level vector wind shear (surface
 321 to 5 km). These quantities are calculated from ARM radiosondes following Wang et al.
 322 (2019).

323 The strength of convection can be quantified in multiple ways. For this study, we
 324 use the intensity of convective cold pools as a proxy for convective strength. The con-
 325 vective cold pool fronts are identified by a rapid decrease of surface equivalent poten-
 326 tial temperature ($\Delta\theta_e$) when the convective cells pass over the ARM sites, followed by
 327 a slow recovery. The cold pool strength is defined as the maximum $\Delta\theta_e$ within a 30-min
 328 time period around the maximum rainfall rate observed by ARM surface rain gauges (Schiro
 329 & Neelin, 2018; Wang et al., 2019). Note that, as in many other profiling radar/satellite/aircraft
 330 studies, we face a challenge due to the possible 'random' nature of the samples. Even
 331 though the selected cases all show mature convective signatures when passing over our

332 radar and surface measurements, we may not ideally sample the center of the precipi-
333 tation/cold pool cores. This could potentially result in an underestimation of precipi-
334 tation rate/cold pool strength.

335 **3 Regional Comparison of Environmental Parameters**

336 **3.1 Thermodynamic Conditions**

337 For each case, we calculate the full set of environmental parameters and generate
338 composite profiles and site summary statistics. In Figure 4, we plot the composite skew-
339 T log- P diagrams (using open source code MetPy; R. M. May et al., 2008 - 2020) from
340 the radiosondes for each ARM site, once again for radiosondes launched prior to convec-
341 tive cores. The green solid lines in Figure 4 represent measured mean dew-point tem-
342 perature profiles, while the red lines are the mean temperature profiles. The overlaid red
343 shading on this figure indicates the mean MUCAPE, while the blue shading is the mean
344 MUCIN. Note that the actual CAPE calculation is based on the virtual potential tem-
345 perature framework, following Bryan and Fritsch (2002). In Figure 5, we plot the dis-
346 tributions of candidate environmental variables for each ARM site, calculated based on
347 the most unstable parcel assuming irreversible ascent. Overall, distinct differences are
348 observed between the associated thermodynamic conditions of interest estimated at the
349 various tropical sites.

350 Among the sites considered, water vapor availability varies significantly. For the
351 sites that are located on tropical islands (GAN, TWP-C1, TWP-C2), large amounts of
352 moisture are available from the Pacific and/or Indian oceans, associated with higher dew-
353 point temperatures throughout the troposphere (Figures 4a-c). On average, the median
354 low-level RHs reach 80% at these sites in the times preceding convection (Figure 5a), which
355 is essential to deep convection onset (e.g., Schiro & Neelin, 2019). Over the Amazon Basin
356 (MAO, Figure 4e), sufficient moistening is also found prior to convection, as a result of
357 the synoptic moisture advection from the Atlantic Ocean (e.g., Drumond et al., 2014;
358 Giangrande et al., 2020, especially during the wet and transitional seasons), water va-
359 por detrained from shallow cumulus convection, as well as the local supply through evap-
360 otranspiration (e.g., Collow et al., 2016; Schiro et al., 2016; Giangrande et al., 2017). Com-
361 pared to the continental-tropical Amazon cases, the maritime continent Darwin compos-
362 ite (TWP-C3) shows a large spread in RH throughout the troposphere (Figure 4d, Fig-

363 ure 5a). This wider distribution reflects the variability through the phases of the north
 364 Australian monsoon season (active and break periods; Pope et al., 2009). During the ac-
 365 tive monsoon, the coastal TWP-C3 site experiences deep westerlies and north-westerly
 366 winds near the surface that bring substantial moisture from the Tropics to northern Aus-
 367 tralia. When the monsoon undergoes its break period, winds become easterly and less
 368 conducive to moisture transport (e.g., Evans et al., 2014). At the continental West Africa
 369 (NIM; Figure 4f) site, relatively less water vapor is available for deep convection (me-
 370 dian low-level RH $\sim 70\%$), and the moisture availability highly depends on the onset/retreat
 371 of the West African monsoon (e.g., Mera et al., 2014).

372 For each site, there is strong evidence for a variety of convection that initiates and
 373 develops uniquely across different thermodynamic environments.

- 374 a) In oceanic environments, the surface/near-surface air parcel does not require sig-
 375 nificant lifting to reach saturation (median LCLs below 0.6 km, Figure 5b) as a
 376 result of the higher moisture availability within the boundary layer. The impli-
 377 cation is that the LFCs are also lower for these cases, which helps promote more
 378 frequent convection (Figure 5c). Rising parcels under these conditions can ideally
 379 extend higher in the troposphere, as suggested by a median LNB_{mu} exceeding 15.7
 380 km (Figure 5j). This contrasts with continental counterparts (MAO and NIM sites),
 381 which suggest a 'skinny' mean MUCAPE profile (e.g., Lucas et al., 1994b, Fig-
 382 ures 4a-c). This LNB distribution is consistent with the LNB map generated us-
 383 ing the A-train satellite dataset in Takahashi et al. (2017).
- 384 b) Over the West African continent (NIM), the pre-convective environment exhibits
 385 an enhanced stable layer with higher LFC (median = 2.1 km) compared to other
 386 island and continental sites (Figure 5c). This stable layer caps the boundary layer
 387 and is associated with a large amount of negative buoyancy (median MUCIN =
 388 -30 J/kg, Figures 4f, 5d). In addition, we observe steeper ELRs (median ELR_{0-3km}
 389 $= 6.3$ °C/km, median $ELR_{3-6km} = 6.2$ °C/km, Figures 5e, f) with parcel tem-
 390 perature largely exceeding the temperature of the surrounding air. This implies
 391 larger parcel buoyancy within the low- and mid-troposphere. As shown in Figure
 392 4f and Figure 5g, the MUCAPE profile composite at NIM has ~ 100 J/kg more
 393 integrated buoyancy at low levels (median LCAPE = 611 J/kg) compared to the
 394 oceanic composites (median LCAPE ≤ 484 J/kg).

395 c) The other continental site MAO and the coastal site TWP-C3 have slightly higher
 396 LFCs (median ≥ 0.8 km) than their oceanic counterparts (median ≤ 0.7 km) that
 397 are associated with larger ranges of CIN values. At the TWP-C3 site, the mon-
 398 soon break period promotes higher CIN values compared to the active phase (e.g.,
 399 M. Pope et al., 2009), which favors isolated deep convection with more intense up-
 400 drafts (e.g., Keenan & Carbone, 1992). Significant shifts in MUCIN and several
 401 other environmental parameters across MAO seasons are also observed in previ-
 402 ous studies (e.g., Giangrande et al., 2017, 2020; Wang et al., 2018). Even though
 403 substantial MUCAPE values are found at all sites before convective initiation (me-
 404 dian ≥ 2651 J/kg; Figure 5h), a large percentage of the MUCAPE extremes are
 405 observed at MAO site with fatter buoyancy profiles throughout the troposphere
 406 (Figure 4e).

407 In terms of the mass detrainment process in deep convection (Figure 5k), every ARM
 408 tropical site exhibits a similar median LMD_{mean} (~ 10 km) but with quantifiable vari-
 409 ability. An exception is the TWP-C3 site, showing the highest median (11.7 km) and
 410 extreme of LMD. LMD is found to be negatively correlated with low-level RH ($r = -0.3$,
 411 not shown), suggesting a higher LMD for cases that developed in a drier condition. How-
 412 ever, the dependence of LMD on other environmental controls such as CAPE is much
 413 weaker ($r < 0.1$, not shown).

414 Consistent with the results of Takahashi and Luo (2012), the mean offsets (LNB_{mu}
 415 minus LMD_{mean} , Figure 5l) for oceanic cases are greater compared to their continen-
 416 tal and coastal counterparts, suggesting larger ε_{proxy} in these systems. When consider-
 417 ing surface, mixed-layer parcels, and irreversible ascent, the ε_{proxy} estimates yield sim-
 418 ilar ocean-land contrast (not shown). Note that the same microphysical assumptions are
 419 used in the parcel theory model for all the tropical sites, without considering the regional
 420 and/or climatological differences. This may add additional uncertainties in the deter-
 421 mination of the LNB and hence the ε_{proxy} estimates.

422 **4 Environmental Conditions Impacting Effective Bulk Entrainment**

423 The large-scale environmental conditions interact with deep convective systems through
 424 the entrainment and mixing processes (e.g., Jensen & Del Genio, 2006; Stirling & Strat-
 425 ton, 2012; Böing et al., 2014). In order to explore the links between different environ-

426 mental factors and the ε_{proxy} , we plot the selected candidate variables discussed in pre-
 427 vious sections as a function of the difference between LNB and LMD (Figure 6). These
 428 quantities are grouped into 1 km increments for our ε_{proxy} . To investigate whether the
 429 relationships are sensitive to the choice of the initial air parcel and the microphysical as-
 430 sumptions in the parcel model that determines LNB and other explanatory factors, we
 431 compare the results using the surface-based parcel (Parcel_{sf}), the most buoyant par-
 432 cel (Parcel_{mu}), and the mixed-layer parcel with irreversible pseudo-adiabatic and reversible
 433 moist adiabatic ascents. The uncertainty in LMD estimation (e.g., usage of LMD_{mean}
 434 versus LMD_{max}) definitions is also considered in the comparison.

435 **4.1 Relationships Between the Environmental Parameters and Effec-** 436 **tive Bulk Entrainment**

437 For the relationships between the environmental parameters and the ε_{proxy} (Fig-
 438 ure 6), the linear correlation coefficients are found to be weak to moderate (i.e., $r \leq 0.6$).
 439 These relationships with CAPE, CIN, and LFC, to a certain extent, are sensitive to the
 440 choice of different originating air parcels, showing slightly higher correlations for quan-
 441 tities calculated using the surface and mixed-layer parcels (not shown) compared to the
 442 most unstable parcel. However, as correlation coefficients are intended for quantities that
 443 are linearly related, these calculations are provided as one reference, but do not fully quan-
 444 tify the complex relationships between entrainment and surrounding environment. Note
 445 that fully isolating entrainment from all the potential contributing factors, the pertur-
 446 bation pressure field in particular, is extremely difficult using existing observational datasets.
 447 However, when considering a reversible ascent of the air parcel, higher correlations are
 448 shown with CAPE, CIN, and LFC, which, to a certain extent, emphasizes the depen-
 449 dence of entrainment on these environmental controls.

450 The CAPE is positively correlated with ε_{proxy} (Figure 6a), suggesting that entrain-
 451 ment and the additional non-adiabatic contributions tend to be more efficient for the events
 452 that have larger CAPE ($r \sim 0.5$ with surface parcels). This is explained due to higher
 453 CAPE corresponding to a larger buoyancy term in the turbulent kinetic energy budget
 454 (e.g., S. B. Pope, 2000; Jensen & Del Genio, 2006). Figures 6b-c show a decrease in the
 455 value of ε_{proxy} when increasing the CIN (CIN increasing to greater negative values) and
 456 the LFC. One explanation for these behaviors is that the CIN and LFC negatively con-
 457 tribute to the total buoyancy, therefore cases with substantial CIN and/or higher LFC

458 tend to be less favorable for mass entraining into the convective updraft regions. The
 459 ELR also shows a negative correlation with ε_{proxy} (Figure 6d). Since a steeper ELR cor-
 460 responds to a 'fatter' buoyancy profile, CAPE concentrates at lower levels and an air par-
 461 cel accelerates more quickly through those levels. This faster accelerating parcel would
 462 reduce the amount of time/exposure for entrainment and other processes to occur.

463 We observe a steady increase in ε_{proxy} with increasing low-level RH (Figure 6e).
 464 A higher RH environment promotes entrainment through its effects on buoyancy pro-
 465 duction of the turbulent kinetic energy (Jensen & Del Genio, 2006; Lu et al., 2018; Stan-
 466 field et al., 2019). In Figure 6f, the ε_{proxy} indicates a negative weak correlation with con-
 467 vective cold pool strength (i.e., $\Delta\theta_e$). This result is consistent with the presence of cold
 468 pools implying the propensity of the atmosphere to promoting deeper and more intense
 469 convection/updrafts that are less impacted by entrainment (e.g., Böing et al., 2012) and
 470 other non-adiabatic processes. Besides, stronger cold pools generated by more intense
 471 convective downdrafts are anticipated to create larger eddies at the gust fronts. These
 472 larger eddies entrain less than the smaller turbulent eddies in the boundary layer (e.g.,
 473 Kuang & Bretherton, 2006; Khairoutdinov & Randall, 2006).

474 In Figure 7, we break down these relationships for oceanic (i.e., GAN, TWP-C1,
 475 TWP-C2) and continental/coastal (i.e., NIM, MAO, TWP-C3) cases. For examples in
 476 Figure 7, only the most unstable parcel followed irreversible ascent is shown on these plots,
 477 and we only consider the LMD_{mean} , as the other previously discussed combinations yield
 478 similar results. Overall, this subset of relationships is in agreement with previous cumu-
 479 lative dataset arguments as shown in Figure 6. The continental/coastal events demon-
 480 strate a slightly higher correlation overall, compared to the oceanic counterparts, how-
 481 ever, this land-ocean contrast becomes minimal when using surface parcels and/or as-
 482 suming reversible moist adiabatic ascent (not shown). Note that, for surface-based cal-
 483 culations, the changes in correlations for continental cases are negligible, as most of the
 484 most unstable parcels are the surface parcels over the land.

485 Other environmental variables of interest (ELR_{0-3km} , LCL, wind shear) all show
 486 weak correlations with ε_{proxy} (not shown). The ELR_{0-3km} is positively correlated with
 487 ε_{proxy} (weak $r \sim 0.2$), since larger ELR_{0-3km} tends to promote higher CAPE ($r = 0.43$,
 488 Figure 8) in the Tropics. The LCL found to have negative correlation with ε_{proxy} (weak
 489 $r \sim -0.2$), as it is highly related to LFC ($r = 0.68$, Figure 8). ε_{proxy} responses to wind

490 shear changes are complex and found to be regime-dependent, with higher correlation
 491 for the continental cases compared to oceanic counterparts (not shown). Note that the
 492 environmental conditions impact ε_{proxy} through their controls on both LNB and LMD.
 493 The CAPE and CIN are found to have a higher correlation with LNB than with LMD
 494 and the low-level RH is found to be more strongly related to LMD than to LNB (not shown).

495 **4.2 Factors Controlling Effective Bulk Entrainment Proxy**

496 There are several ongoing challenges related to how the entrainment and other non-
 497 adiabatic processes in deep convection respond to changes in environmental conditions,
 498 and which environmental or thermodynamic quantities of interest have the greatest pre-
 499 dictive capabilities to inform on those processes (e.g., Hannah, 2017). For this study, we
 500 use a Random Forest (RF) method to investigate the importance of several candidate
 501 quantities in explaining the observed ε_{proxy} in deep convection. The RF regression al-
 502 gorithm (Breiman et al., 1984; Quinlan, 1993) is an ensemble-learning algorithm that
 503 combines a large set of regression trees. The main advantages to applying RF methods
 504 to address this question is that these methods handle non-linear parameters efficiently,
 505 require no feature scaling, and have a low overfitting risk (Breiman, 2001). We accom-
 506 plish this using the open-source Scikit-learn’s RF regression algorithm (toolkit from Pe-
 507 dredosa et al., 2011). We optimize the RF approach by tuning two important param-
 508 eters, the number of regression trees and the number of inputs per node. After perform-
 509 ing these sensitivity tests, 500 regression trees are included in the RF with 5 inputs per
 510 node, since this combination yields the lowest root mean square error for our particu-
 511 lar application.

512 The RF regression algorithm reports the feature importance score for each input
 513 quantity (e.g., Breiman, 2001; Liaw & Wiener, 2002). As shown in Figure 9a, the MU-
 514 CAPE and low-level RH exhibit higher feature importance scores (0.19 and 0.17) com-
 515 pared to other candidates, indicating these indices as more important to quantifying ε_{proxy}
 516 in tropical deep convection. This finding is consistent with the previous work by Jensen
 517 and Del Genio (2006) for tropical cumulus congestus clouds observed at Nauru (TWP-
 518 C2). Other environmental variables suggest relatively lower feature importance, with the
 519 implication that these quantities are not informative to the governing factors for the ε_{proxy}
 520 in tropical deep convective clouds. When considering calculations based on other initial

521 parcels (i.e., surface- and mixed-layer), CAPE always obtains the highest feature impor-
 522 tance score compared to other environmental variables.

523 The feature importance scores have been separately calculated for the oceanic and
 524 continental event observations (Figures 9b-c). For the continental cases, in addition to
 525 MUCAPE and low-level RH, the vertical wind shear reports a relatively higher feature
 526 importance score. Again, this suggests that low-level wind shear provides greater impor-
 527 tance in determining the ε_{proxy} compared to the oceanic cases. For the continental cases,
 528 one interpretation is that strong vertical wind shear promotes more interactions with the
 529 updrafts, and affects the vertical acceleration (e.g., Peters et al., 2019). When assum-
 530 ing reversible moist adiabatic ascent, CAPE remains the most important feature to the
 531 ε_{proxy} prediction. However, CIN is found to be equally important compared to vertical
 532 wind shear in determining ε_{proxy} for continental cases.

533 Note that the RF approach could potentially underestimate the contribution of cer-
 534 tain quantities as a predictor when they are correlated with other inputs, even though
 535 this effect is somewhat reduced owing to random selection of inputs at each node cre-
 536 ation. On the other hand, this is one of the advantages of using RF for reducing over-
 537 fitting problems, since it removes features that are mostly duplicated by other features.

538 5 Conclusions

539 This study summarizes the characteristics and regional variations of the outflow
 540 heights (LNB, LMD) and, by proxy, the ε_{proxy} (LNB minus LMD) in tropical deep con-
 541 vective clouds. Note that, when assuming irreversible pseudo-adiabatic ascent in the LNB
 542 calculation, this ε_{proxy} includes the effects of processes other than entrainment (e.g., con-
 543 densation loading and pressure perturbation forces) that also impact the buoyancy in
 544 convective updrafts. We further investigate the contribution of condensation loading by
 545 including reversible moist adiabatic ascent in the parcel model. The subsequent inves-
 546 tigation explores how the ε_{proxy} is related to the pre-convection environmental condi-
 547 tions using observations obtained from six ground-based DOE ARM sites in the Trop-
 548 ics. These multi-year datasets provide a considerable number of cases from diverse trop-
 549 ical environments including long-term observations from the Tropical Western Pacific
 550 Ocean (TWP-C1, TWP-C2, TWP-C3), West Africa (NIM), the Amazon basin (MAO),
 551 and the Indian ocean (GAN).

552 The key findings of this study are as follows:

- 553 a) Oceanic deep convective systems occur in a moist environment (median low-level
 554 RH \sim 80%) with near-surface LCL and LFC. 'Skinny' CAPE profiles are found
 555 preceding convection, with small buoyancy accumulated at low levels (median LCAPE
 556 \sim 440 J/kg), which matches those observed in previous oceanic examples (e.g.,
 557 Lucas et al., 1994b, 1994a).
- 558 b) Pre-convection soundings over the continent feature higher LCLs, LFCs, and steeper
 559 ELRs. These conditions lead to a more significant CIN and larger LCAPE. The
 560 most pronounced examples for this are observed for the West Africa (NIM) datasets,
 561 where the vertical wind shear is also found to be stronger. Reduced lower-tropospheric
 562 water vapor is available for the continental cases compared to their oceanic coun-
 563 terparts.
- 564 c) Median LNBs (using irreversible pseudo-adiabatic ascent) in oceanic events ex-
 565 ceed 15.7 km, with the maximum height (16.2 km) at Nauru Island (TWP-C2)
 566 in the Equatorial Pacific Ocean. Assuming reversible moist adiabatic ascent low-
 567 ers the mean LNB by 2.5 km. In terms of LMD, all tropical sites exhibit a sim-
 568 ilar median value (\sim 10 km). The exception is the Darwin (TWP-C3) site, where
 569 the LMD extends higher and to 11.7 km on average, due to those low RH extremes.
 570 The LNB and LMD differences (i.e., ε_{proxy}) are found to be greater in oceanic cases
 571 compared to those in continental and coastal events. This finding is consistent with
 572 previous studies by Zipser (2003) and Takahashi et al. (2017).
- 573 d) The ε_{proxy} varies depending on the environmental humidity and stability. Deep
 574 convective clouds that occur during periods with larger CAPE and/or higher low-
 575 level RH tend to have larger differences between the LMD and LNB. This behav-
 576 ior suggests larger ε_{proxy} and more dilution of the convective updrafts for those
 577 conditions. In contrast, the suggestion is that more stable conditions with larger
 578 CIN/steeper ELR/higher LFC tend to suppress the ε_{proxy} . Similarly, we find that
 579 events that produce stronger convective cold pools at the surface apparently ex-
 580 perience reduced ε_{proxy} . For all the parameters considered (based on application
 581 of a RF regression approach), CAPE has the highest feature importance score in
 582 determining the ε_{proxy} , followed by low-level RH. The vertical wind shear and CIN
 583 also indicate increased importance in their role in controlling ε_{proxy} for continen-
 584 tal deep convective clouds.

585 This study advances our understanding of the interaction between tropical deep
586 convection and its surrounding environment, and which atmospheric conditions are fa-
587 vorable for buoyancy reducing processes (e.g., entrainment) on convective updrafts. The
588 relationships between the ε_{proxy} and environmental variables have potential uses in con-
589 vection parameterization development and provide further constraints to climate mod-
590 els. For example, as the CAPE is by far the most important environmental control for
591 ε_{proxy} prediction, the CAPE profile and/or amount could be used as a scaling factor for
592 the lateral entrainment rates in the models. In addition, lateral entrainment rates that
593 are a function of RH may be appropriate since it has been found to have the second high-
594 est feature importance in ε_{proxy} prediction.

Acknowledgments

This project was supported by the U.S. Department of Energy (DOE) Atmospheric System Research (ASR) program, the Climate Model Development and Validation (CMDV) program, and the Office of Workforce Development for Teachers and Scientists (WDTS) under the Science Undergraduate Laboratory Internships Program (SULI). This paper has been authored by employees of Brookhaven Science Associates, LLC, under contract DE-SC0012704 with the U.S. DOE. The publisher by accepting the paper for publication acknowledges that the U.S. Government retains a nonexclusive, paid-up, irrevocable, worldwide license to publish or reproduce the published form of this paper, or allow others to do so, for United States Government purposes. We also acknowledge the Atmospheric Radiation Measurement program, a user facility of the U.S. DOE, Office of Science, sponsored by the Office of Biological and Environmental Research, and support from the ASR program of that office. Dr. Mullendore was partially supported by National Aeronautics and Space Administration (NASA) Grant 80NSSC19K0343. Dr. Luo would like to acknowledge support by NASA grants 80NSSC17K0197 and 80NSSC20K0089.

The authors declare that there is no conflict of interest regarding the publication of this article.

Data availability: All ARM data sets used for this study are available through the ARM discovery website <https://adc.arm.gov/discovery/>.
