24 **Abstract**

25 Plant functional diversity is strongly connected to photosynthetic carbon assimilation in  
26 terrestrial ecosystems. However, many of the plant functional traits that regulate photosynthetic  
27 capacity, including foliar nitrogen concentration and leaf mass per area, vary significantly  
28 between and within plant functional types and vertically through forest canopies, resulting in  
29 considerable landscape-scale heterogeneity in three dimensions. Hyperspectral imagery has been  
30 used extensively to quantify functional traits across a range of ecosystems but is generally  
31 limited to providing information for top-of-canopy leaves only. On the other hand, lidar data can  
32 be used to retrieve the vertical structure of forest canopies. Because these data are rarely  
33 collected at the same time, there are unanswered questions about the effect of forest structure on  
34 the 3-D spatial patterns of functional traits across ecosystems. In the United States, the National  
35 Ecological Observatory Network's Airborne Observation Platform (NEON AOP) provides an  
36 opportunity to address this structure-function relationship by collecting lidar and hyperspectral  
37 data together across a variety of ecoregions. With a fusion of hyperspectral and lidar data from  
38 the NEON AOP and field-collected foliar trait data, we assessed the impacts of forest structure  
39 on spatial patterns of N. In addition, we examine the influence of abiotic gradients and  
40 management regimes on top of canopy %N and total canopy N (i.e. the total amount of N ( $\text{g}/\text{m}^2$ )  
41 within a forest canopy) at a NEON site consisting of a mosaic of open longleaf pine and dense  
42 broadleaf deciduous forests. Our resulting maps suggest that in contrast with top-of-canopy  
43 values, total canopy N variation is dampened across this landscape resulting in relatively  
44 homogeneous spatial patterns. At the same time, we found that leaf functional diversity and  
45 canopy structural diversity showed distinct dendritic patterns related to the spatial distribution of  
46 plant functional types.

## 70 1. INTRODUCTION

71 The relationship between forest structure and function is a major focus of ecosystem  
72 ecology; however, most studies have focused on measurements within traditional forest plots  
73 (Ellsworth and Reich 1993; Parker et al. 2004; Gough et al. 2019; Atkins et al. 2018; Fahey et al.  
74 2015; Pedro et al. 2017). These studies have shown that the integral relationship between  
75 structure and function drives important canopy processes such as net photosynthetic carbon  
76 assimilation (Niinemets 2007), resource use and efficiency (Hardiman et al. 2013), and woody  
77 growth (Stark et al. 2012), as well as critical ecosystem processes such as net primary production  
78 (Scheuermann et al. 2018; Hardiman et al. 2011). Since the individual traits that drive this  
79 structure-function relationship are not constant in space and instead show significant  
80 heterogeneity across landscapes (Chambers et al. 2007; Asner et al. 2014), a core question in  
81 ecosystem ecology is: Do landscape scale patterns of forest functional traits change when whole  
82 plant structure is considered?

83 In addition to this significant spatial variation, plant functional and structural traits also  
84 vary in three-dimensional space due to a host of different long-term abiotic growth conditions,  
85 crown position within the canopy and competition for light, as well as within-canopy fluctuating  
86 light environments across the full vertical and horizontal extent of the canopy (the ‘canopy  
87 volume’; Ellsworth et al. 1993). These differing light and growth environments drive variation of  
88 important leaf functional traits including leaf mass per area (LMA; the ratio between leaf dry  
89 mass and leaf area) and foliar nitrogen (foliar N;  $g/m_G^2$ ;  $m_G$  = meter of ground) within the  
90 canopy volume (Poorter et al. 2009, Niinemets, 2007). Moreover, horizontal and vertical patterns  
91 of these traits in growth environments create heterogeneous distributions of leaves in three  
92 dimensions causing significant variation in canopy-scale carbon assimilation across plant

93 functional types (Niinemets 2015). This variation can be attributed to differing light  
94 environments related to the effects of multiple scattering, within-canopy shading, and the density  
95 of plant material above and around a given leaf (Stark et al. 2012; Harding et al. 2001).  
96 Resulting tradeoffs between light interception, photosynthetic capacity, and construction costs  
97 (e.g. the leaf economics spectrum) leads to broadly predictable variation in photosynthetic  
98 strategies across the plant species comprising global terrestrial biomes (Reich et al. 1997; Wright  
99 et al. 2004).

100         At the canopy scale, forest structural traits can be used to describe the architectural  
101 properties that define a leaf's growth environment. These traits include leaf area density (LAD;  
102 the total leaf area per unit of volume) which characterizes the horizontal and vertical spatial  
103 variation of leaf area within a canopy (Weiss et al. 2004) and canopy clumping (a measure of  
104 foliage aggregation relative to a random spatial distribution of leaf material within the canopy;  
105 Pisek et al. 2018). When combined with information on plant function, structural diversity yields  
106 important insights into vegetation growth and carbon cycling (Niinemets 2012), however both  
107 can be challenging to quantify at scales larger than vegetation plot without advanced remote  
108 sensing technologies (Asner and Martin 2009).

109         Remote sensing has played a significant role in understanding the global terrestrial  
110 carbon cycle for decades (Tucker and Sellers 1986; Schimel 1995; Running et al. 2004; Schimel  
111 et al. 2015), with a more recent focus on the use of hyperspectral imagery and lidar to measure  
112 forest function and structure. By utilizing hundreds of narrow spectral bands, airborne passive  
113 optical hyperspectral imagery (HSI; also known as imaging spectroscopy) provides detailed two-  
114 dimensional (2D) information on the spectral and functional properties of leaves at the top of the  
115 canopy (Ollinger et al. 2002; Townsend et al. 2003; Asner et al. 2015; Singh et al. 2015; Dahlin

116 et al. 2013). Lidar is an active remote sensing system that utilizes laser pulses to measure  
117 distance, which can then be used to accurately estimate the three dimensional (3D) and internal  
118 structure of forest canopies across a range of plants in different biomes (Stark et al. 2012;  
119 Kamoske et al. 2019; Shao et al. 2019; Smith et al. 2019). While passive optical data can also be  
120 used to estimate variables related to forest structure, including clumping index (Pisek et al. 2018)  
121 and 3D point clouds through structure-from-motion methods (Dandois et al., 2013; Iglhaut et al.  
122 2019), the results are not as robust as active methods like lidar for generating 3D plant  
123 information. Compared to HSI data, lidar can yield detailed insights into plant architecture but  
124 does not provide the information necessary to map leaf functional traits across space and time, a  
125 combination of these data sources is required to provide a complete picture of vegetation  
126 structural and functional diversity. However, few publicly-available opportunities and platforms  
127 exist for the simultaneous collections of these two complementary technologies (Cook et al.  
128 2013, Kampe et al. 2010), limiting our ability to combine landscape-scale information about  
129 forest structural and functional traits that play critical roles in whole-canopy processes like  
130 carbon assimilation.

131         In this study, we take steps towards addressing the question of how leaf traits and  
132 structural heterogeneity determine whole canopy function by considering how spatial patterns of  
133 top of canopy and total canopy traits vary across a heterogeneous landscape. We detail a  
134 reproducible methodology for estimating functional and structural diversity within the canopy  
135 volume from airborne lidar and hyperspectral data from the National Ecological Observatory  
136 Network's Airborne Observation Platform (NEON AOP; Kampe et al. 2010). We compare the  
137 spatial patterns of 3D whole canopy traits derived from our fusion of lidar and hyperspectral data  
138 with traditional 2D remote sensing derived top of canopy traits. In addition, we examine the

139 influence of topography, geology, and management regimes on these two measurements of  
140 functional diversity at a NEON site consisting of patches of open longleaf pine and dense  
141 broadleaf deciduous forests, located in Alabama, USA. These insights could lead to a better  
142 understanding of how we scale fine-resolution ecological processes to landscape, continental,  
143 and global models (Schimel et al. 2019).

## 144 **2. MATERIALS AND METHODS**

### 145 *2.1 Site Description*

146 Field measurements and remote sensing data were acquired in Talladega National Forest –  
147 Oakmulgee Ranger District (TALL) in west-central Alabama, USA (Figure 1). TALL is a core  
148 NEON site covering 5,300 hectares with a mean annual temperature of 17° C and a mean annual  
149 precipitation of 1350 mm. TALL consists of a mosaic of forest types, with higher elevation areas  
150 containing an overstory of longleaf pine (*Pinus palustris*) and loblolly pine (*Pinus taeda*), while  
151 white oak (*Quercus alba*), Southern red oak (*Quercus falcata*), chestnut oak (*Quercus montana*),  
152 blackjack oak (*Quercus marilandica*), mockernut hickory (*Carya tomentosa*), pignut hickory  
153 (*Carya glabra*), sweetgum (*Liquidambar styraciflua*), and tulip tree (*Liriodendron tulipifera*) are  
154 present in lower elevation bottomlands. TALL is an actively managed site with ongoing logging,  
155 restoration, and prescribed burning projects (USDA Forest Service 2005).

### 156 *2.2 Airborne Remote Sensing Data*

157 The NEON AOP collected remotely sensed data from April 27 to April 29, 2018 at TALL. The  
158 NEON AOP employs a full-range hyperspectral sensor (380 to 2500 nm; 5 nm bands), a high-  
159 resolution RGB camera, and a lidar system (Kampe et al. 2010). Flights occurred at an altitude of  
160 1000m, resulting in hyperspectral measurements at a one-meter resolution. The lidar system for  
161 this collection was a Riegl Q780 Laser Measurement System operated at a scan angle of +/- 18

162 degrees, and a beam divergence of 0.8 mRad, resulting in an average point density of 9.48  
163 pts/m<sup>2</sup>.

### 164 *2.3 Field Data Collection and Lab Methodologies*

165 In May 2018, shortly after the AOP collection, we collected leaves from throughout the canopy  
166 volume, targeting the dominant species at TALL (10 species total; listed in section 2.1). Foliar  
167 samples were collected using a Big Shot line launcher (SherrillTree, Greensboro, NC) and a pole  
168 pruner, with each sample's height estimated using a laser range finder and meter marks on the set  
169 line. We collected sample locations using a Trimble GEO7x GPS (Trimble, Sunnyvale, CA),  
170 which were later differentially corrected with Trimble's GPS Pathfinder Office software. As we  
171 collected samples from the canopy, they were wrapped in a damp paper towel, sealed in a plastic  
172 bag, and placed in a cooler with ice packs. In total we collected 156 foliar samples from the  
173 canopy dominant species (Appendix S1: Fig. S1 and Fig. S2). In addition to leaf samples, we  
174 took 120 hemispherical photographs across the site, following the protocol described in  
175 Kamoske et al. (2019).

176 Leaf samples were processed the same day in our mobile laboratory. For each sample (a  
177 small branch with multiple leaves) we took three reflectance measurements from different leaves  
178 with a SVC HR-1024i Spectroradiometer with an attached LC-RP-Pro leaf clip foreoptic  
179 (Spectra Vista Corporation, Poughkeepsie, NY) , which collects data from 340 to 2500 nm with a  
180 bandwidth of approximately 2 nm. Leaves from broadleaf samples were placed directly into the  
181 leaf clip, while we created mats from needleleaf samples by laying the needles vertically next to  
182 one another while taping the ends together. For needleleaf samples, only the needles and not the  
183 taped ends were placed into the leaf clip. After each sample, the instrument was recalibrated  
184 using a white Spectralon panel. We then collected a minimum of 500 mg of leaf material from

185 the sample using a pair of scissors that were sterilized between each sample. These pieces of leaf  
186 material were imaged on a flatbed scanner and processed for area using imageJ software  
187 (Schneider et al. 2012). We placed the leaf material in a paper coin envelope and dried the  
188 samples at 70° C for at least 48 hours. After drying, we weighed the leaf samples and calculated  
189 leaf mass per leaf area (LMA;  $\text{g}/\text{m}_L^{-2}$ ;  $\text{m}_L$  = meter of leaf material). A subset of these samples (n  
190 = 40, ~4 per species) were re-dried, ground to a fine powder using a ball mill (2000 Geno  
191 Grinder; Spex Sample Prep, Cridersville, OH, USA), with 1.50-2.50 mg weighed in 0.1-mil tin  
192 foil vials (AX26DR; Mettler Toledo, Columbus, OH, USA), and used to determine the C:N ratio  
193 and elemental N content (g N/g leaf, %) employing a CHNS/O elemental analyzer operated in  
194 CHN mode, according to the manufacturer's instructions (2400 Series II CHNS/O Analyzer;  
195 Perkin Elmer, Waltham, MA, USA) at Brookhaven National Laboratory (Upton, NY).

196 To build a leaf-scale model of %N to apply to the remaining samples in lieu of  
197 determining foliar N in the lab, we used the laboratory calculated %N values and the associated  
198 mean reflectance values for each wavelength, to train a partial least squares regression model  
199 (PLSR; Serbin et al. 2014; Singh et al. 2015). We withheld 20% of the samples using a weighted  
200 random approach, based on the %N values, as validation data (n = 8) that wasn't used to develop  
201 the model and used the remaining samples (n = 32) as model training data. Using a jackknife  
202 approach that randomly withholds 20% of the training data through 50 iterations, we calculated a  
203 PRESS statistic (up to 15 components) for each iteration. We then selected the number of  
204 components for our final model using the lowest PRESS statistic that balanced predictive  
205 accuracy between the training and validation datasets. We applied these equations to the  
206 validation data to assess model accuracy. We then applied the final PLSR coefficients to the  
207 reflectance measurements of all 156 leaf samples to determine PLSR derived %N values. We

208 used the PLSR predicted values in subsequent analysis. This methodology follows the process  
209 and code described in Serbin et al. (2014), with all analysis performed in R using the pls package  
210 (Mevik and Wehrens 2015).

#### 211 *2.4 Lidar Methods*

212 Lidar data was processed for LAD ( $m_L^2/m_G^3$ ;  $m_G$  = meter of ground) at a 10x10 meter spatial  
213 resolution using the canopyLazR package on GitHub (Kamoske et al. 2019). The canopyLazR  
214 package uses the methods described by MacArthur and Horn (1969) and is similar to other  
215 published methods (Stark et al. 2012; Zhao and Popescu 2009; Solberg et al. 2006; Sumida et al.  
216 2009). By normalizing the point cloud to height above ground, LAD is calculated by counting  
217 the number of lidar pulses that enter and exit each voxel in each vertical column of data that has  
218 at least one ground return. After removing the bottom 10 meters of the canopy due to noise  
219 caused by topographic variation (Kamoske et al. 2019), a stack of rasters containing LAD  
220 estimates for each 1-meter slice of the canopy above this threshold is returned (mean canopy  
221 height at TALL is 25 meters). LAI is then calculated by taking the sum of LAD values within a  
222 given column of voxels within the canopy. While the TALL lidar data set has a considerably  
223 higher point density than the NEON lidar data used in Kamoske et al (2019), here we elected to  
224 keep this relatively conservative approach to aggregating and filtering these data as these lidar  
225 point clouds were processed as part of a larger study where we wanted to maintain data  
226 uniformity across sites. Moreover, topographic issues have been shown to be common when  
227 using lidar data for DEM generation (Bater and Coops 2009), which are further amplified when  
228 using low-density lidar data. To calibrate the lidar derived LAI estimates to field collected data,  
229 we processed field-collected hemispherical photographs for LAI using the DHP software  
230 (Leblanc et al. 2005). We then calculated the slope of a regression equation between these

231 measurements and the lidar derived LAI estimates (Appendix S1: Fig.S8; Sabol et al. 2014;  
232 Richardson et al. 2009). This slope is used as an extinction coefficient in the Beer-Lambert  
233 portion of the LAD equation described in Kamoske et al. (2019) and in Appendix S1: Fig. S8.  
234 For TALL we used an extinction coefficient of 0.4982. Here we opted to use a single extinction  
235 coefficient for the entire site, rather than separate coefficients for broadleaf, needleleaf, and  
236 mixed species pixels due to difficulties in detecting species differences with lidar data.

237         Based on our previous work in Kamoske et al. (2019), we then applied a canopy height  
238 and LAI mask to each processed LAD raster to minimize noise in the lidar dataset. Using  
239 Tukey's outlier test ( $k = 1.5$ ), we removed all outliers from the upper end of the dataset, which  
240 resulted in all pixels with a canopy height greater than 44 meters being removed as well as all  
241 pixels with a LAI value greater than 6 (0.002% of pixels). While a LAI value of 6 is a statistical  
242 output, it is also greater than our highest field-collected plot-scale LAI value of 4.35. We also  
243 removed all pixels with a LAI value equal to 0. Using these masked LAD tiles, we calculated 26  
244 lidar derived forest structural attributes in raster format at a 10x10 meter resolution. These  
245 include filled canopy volume, canopy porosity, and canopy distribution metrics described in  
246 Hardiman et al. (2013), top of canopy rugosity, and canopy euphotic, oligophotic, and empty  
247 zone metrics described in Lefsky et al. (1999), canopy height metrics described in Shi et al.  
248 (2018), and within canopy rugosity described in Hardiman et al. (2011). All code to calculate  
249 these metrics is provided in the canopyLazR package on our GitHub page  
250 (<https://github.com/akamoske/canopyLazR>; <http://doi.org/10.5281/zenodo.3987340>). An overall  
251 diagram of our workflow is shown in Figure 2.

## 252 *2.5 Hyperspectral Imagery Methods*

253 We processed the atmospherically corrected, HSI reflectance data before analysis. First, we  
254 removed all flight lines from April 27 due to cloudiness, as well as the horizontal (east-west)  
255 flight lines from April 29 and April 30. The remaining north-south flight lines covered the entire  
256 TALL site (April 29 and April 30 flights covered the same area as the April 27 flights). Next, we  
257 visually identified noisy bands in the dataset and removed all bands that were below 500 nm,  
258 between 1350 and 1450 nm, between 1800 and 2000 nm, and all bands above 2400 nm. We then  
259 calculated a narrowband NDVI mask (red = 674 nm; NIR = 830 nm;  $NDVI > 0.5$ ) to remove all  
260 non-vegetated pixels from further analysis (Dahlin et al. 2014). We used this relatively high  
261 NDVI value of 0.5 in order to leave only healthy green vegetated pixels during the subsequent  
262 corrections and analysis. We also calculated a brightness mask to remove all shaded pixels using  
263 Tukey's outlier test ( $k = 1.5$ ), where all pixels that have a reflectance below this cutoff at 800 nm  
264 are considered outliers and removed. This is a modified version of the methodologies presented  
265 by Clark et al. (2005) and Gougeon (1995), which removes all pixels that are less than the mean  
266 reflectance value at 800nm. Following this, we applied a topographic correction to reduce the  
267 effects of terrain, view, and illumination on the reflectance data by normalizing the sunlit area  
268 within a pixel without changing the sun and sensor positions or the orientation, geometry, and  
269 structure of the canopy while also accounting for diffuse radiation (Soenen et al. 2005). Lastly,  
270 we applied a bidirectional reflectance distribution function effects correction (BRDF) with a  
271 thick Ross kernel and a dense Li kernel to remove the anisotropic scattering properties of  
272 vegetation that result in flight line artifacts (Colgan et al. 2012; Collings et al. 2010; Schlapfer et  
273 al. 2015; Wanner et al. 1995; Weyermann et al. 2015). Annotated R code to apply these  
274 corrections is available on our GitHub page as the hypRspec package  
275 (<https://github.com/akamoske/hypRspec>; <https://zenodo.org/record/3987336>).

276 From the resulting images, we extracted reflectance data for all top of canopy field  
277 samples. Due to potential image orthorectification errors, GPS uncertainty, and field challenges,  
278 we visually assessed GPS point locations and, when necessary, moved the GPS locations, by  
279 hand, 1-2 meters to the most appropriate pixel based on a canopy height model and pixel  
280 brightness. Due to flight line overlap, many samples had multiple reflectance values. In these  
281 cases, we kept the reflectance data from whichever image produced the brightest total reflectance  
282 across all bands. We choose to take the brightest reflectance value rather than the median here, in  
283 order to filter pixels that were possibly affected by collection issues related to adverse weather  
284 conditions that would not be resolved during the topographic and BRDF correction process.

285 Once reflectance spectra for all top of canopy samples ( $n = 52$ ) were extracted, we  
286 developed PLSR models for top of canopy %N and LMA (Ollinger et al. 2002; Townsend et al.  
287 2003; Singh et al. 2015) using the same methodology and code described for the laboratory data.  
288 For the LMA model, we removed all lab measured LMA values that were greater than  $259 \text{ g/m}^2$   
289 based on the results from a Tukey's extreme outlier test ( $k = 3$ ). This outlier test removed 6  
290 samples from the dataset. We removed these outliers from the dataset prior to fitting our models,  
291 due to PLSR being sensitive to outliers during the calibration and validation process (Martens  
292 and Martens 2000). Once PLSR coefficients were calculated for top of canopy LMA and %N,  
293 we applied them to the corrected HSI data, resulting in a 1x1 meter raster for each trait (%N and  
294 LMA). We then filtered the trait maps to remove all extreme outlier pixels ( $k = 3$ ) and values less  
295 than 0 from each 1x1 meter raster that result from the errors associated with reflectance values  
296 collected during image collection. This resulted in 0.09% of the pixels being removed from the  
297 final raster. Next, we resampled the mosaicked image to a 10x10 meter spatial resolution using  
298 the mean value within a given kernel, to match the spatial resolution of the lidar derived rasters.

299 Following this, we mosaicked the flight line rasters together with the mean of overlapping pixels  
300 used in the final raster. All analysis was performed in the R programming language and is  
301 available on our GitHub page as the hypRspec package (<https://github.com/akamoske/hypRspec>,  
302 <https://zenodo.org/record/3987336>).

### 303 *2.6 Remote Sensing Fusion: Total Canopy N*

304 To model within canopy LMA, we extracted data from the 26 previously calculated lidar  
305 structural attribute rasters, and top of canopy %N and LMA rasters, for all 156-field sample  
306 locations. We also included the height and depth (e.g. distance from the top of canopy) for each  
307 of the samples in the model. We then removed all top of canopy samples (n = 52) since these  
308 were used in previous steps and were predicted using the HSI data and PLSR. We then tested the  
309 correlation (Pearson's R) between each variable and within canopy LMA. To avoid  
310 multicollinearity, variables with correlations greater than 0.5 to each other were considered too  
311 correlated and the predictor most correlated with LMA was kept for further analysis. We then  
312 split the dataset into validation data (20%; n = 20) and training data (80%; n = 84) using a  
313 weighted approach based on species sample counts. Using the previously determined variables  
314 we developed an ordinary least squares (OLS) regression model from the training data. To  
315 determine the best combination of variables for our final model predicting within canopy LMA,  
316 we used backwards stepwise AIC model selection (Burnham et al. 2011; Mascaro et al. 2011).  
317 We then applied the resulting coefficients to the validation dataset to examine the overall  
318 predictive accuracy of our model. Because we did not see a substantial variation of within  
319 canopy %N in our data (Appendix S1: Fig.S1) or in the literature (Serbin et al. 2014; Bachofen et  
320 al. 2020), we used top of canopy %N values for our within canopy %N values in lieu of creating  
321 another predictive model.

322 We then applied the final model coefficients to the raster data to create a three-  
323 dimensional model of within canopy LMA ( $\text{g/m}_L^2$ ), with any value less than zero set to NA (due  
324 to predictive inaccuracy and noise in the raster data). Lastly, we used these three-dimensional  
325 models to calculate within canopy N per meter of ground area ( $\text{g/m}_G^2$ ;  $\text{m}_G$  = meter of ground)  
326 using the following equation:

$$327 \quad N_{tot} = \sum_{i=10}^h N_{TOC} * LMA_i * LAD_i$$

328 where  $N_{tot}$  is the total canopy N ( $\text{g/m}_G^2$ ) for each 10x10 meter pixel,  $i$  refers to each 1 m layer of  
329 the canopy, starting at 10 m (layers below 10 m were not considered in this analysis),  $h$  is the  
330 maximum height of each column of voxels,  $N_{TOC}$  is the top of canopy N (%),  $LMA_i$  is the LMA  
331 at each voxel  $i$  ( $\text{g/m}_L^2$ ) and  $LAD_i$  is the LAD at each voxel  $i$ . This resulted in a two-dimensional  
332 raster for the entire AOP collection area that summarizes functional and structural traits within  
333 the canopy volume. We also calculated foliar biomass using the same equation described above  
334 but withholding the  $N_{TOC}$  values. Lastly, we removed all extreme outliers from the raster images  
335 using Tukey's outlier test ( $k = 3$ ). All analysis was performed in the R programming language.

### 336 *2.7 Raster Differences Across Scales*

337 To test whether the distinction between leaf-level and canopy traits was scale dependent, we  
338 tested the differences between the top of canopy and total canopy N rasters at multiple spatial  
339 grains. First, we scaled the original 10x10 meter data to 30x30 and 250x250 meter resolutions to  
340 match Landsat and MODIS pixels using the raster package in R (Hijmans 2019). Next, we  
341 randomly extracted 10,000 points from the 10x10 m and 30x30 m rasters and 1,000 points from  
342 the 250x250 m raster. We then used a linear regression to test the correlations between the two  
343 rasters at each spatial resolution. To compare the spatial patterns of the two rasters, we scaled

344 and centered the rasters using the scale function in the raster package and then subtracted the  
345 normalized total canopy N raster from the normalized top of canopy %N raster.

346 To compare the overall spatial patterns of the two maps, we extracted 10,000 random  
347 points from the top of canopy and total canopy rasters at the 10x10 m resolution and fit  
348 variograms to these samples. We compared estimates of spatial autocorrelation as well as  
349 differences in the nugget, sill, and range of the variograms.

### 350 *2.8 Environmental Driver Analysis*

351 To understand the influence of abiotic gradients and management practices on the spatial  
352 patterns of top of canopy %N and total canopy N ( $\text{g/mG}^2$ ), we assessed and analyzed the spatial  
353 patterns of the data, using multiple regression and Moran's I to test these relationships.

354 To quantify the abiotic gradients and management practices, we calculated 26  
355 topographic, geologic, and management variables using ArcGIS, QGIS, and R (Appendix S1:  
356 Fig.S7). Topographic variables were calculated from the 10x10 meter lidar data, geologic  
357 variables were downloaded from the USGS (Horton 2017), and management variables were  
358 downloaded from the US Forest Service (<https://data.fs.usda.gov/geodata/edw/datasets.php>). All  
359 variables were transformed into rasters for subsequent analysis.

360 We performed a Monte Carlo test with 1,000 simulations to calculate a distribution of  
361 model coefficients, Moran's I of the residuals, and  $R^2$ . During each simulation, we extracted  
362 10,000 random points from the rasters. We then standardized all non-binary variables (Gelman  
363 2007; mean = 0, standard deviation = 0.5) to allow direct comparison between model  
364 coefficients. We developed two regression models, one for top of canopy %N and one for total  
365 canopy N ( $\text{g/mG}^2$ ). For each simulation and for each regression model we used the following  
366 methodology. First, we tested the correlation between each variable (Pearson's R) to avoid

367 multicollinearity, with correlations greater than 0.5 considered to be too correlated and the  
368 predictor most correlated with N kept for further analysis. Using the remaining variables, we  
369 developed an OLS regression equation. With these results, we used backwards stepwise AIC  
370 model selection to determine the best combination of variables for each of our final models. Any  
371 remaining variables with non-significant coefficients ( $p$ -value  $> 0.05$ ) were then removed. We  
372 then used these variables in a final OLS regression. To test for spatial autocorrelation, we  
373 calculated Moran's I on the model residuals. All analysis was performed with the R  
374 programming language.

### 375 **3. RESULTS**

#### 376 *3.1 Trait Prediction with PLSR: From Leaf to Canopy*

377 To predict leaf level %N, we used a PLSR model with five components to produce the best  
378 results between training and validation data (Table 1; Appendix S1: Fig.S3). This model had an  
379  $R^2$  of 0.90 for the training data, an  $R^2$  of 0.78 for the validation data, and an  $R^2$  of 0.87 when  
380 applied to all the data. All models had a  $p$ -value  $< 0.001$ . Across the lab-measured %N samples,  
381 values ranged from 0.55 to 2.64% and PLSR-predicted values ranged from 0.40 to 2.64%. For  
382 subsequent steps, we used PLSR-predicted values.

383 To predict the top of canopy %N from the HSI data, we used a PLSR model with five  
384 components. This model had an  $R^2$  of 0.61 for the training data, an  $R^2$  of 0.57 for the validation  
385 data, and an  $R^2$  of 0.56 when applied to all the data (Table 1; Appendix S1: Fig.S4). All models  
386 had a  $p$ -value  $< 0.001$ . After applying the PLSR coefficients across the images and removing  
387 extreme outliers using a Tukey's outlier test ( $k = 3$ ), %N values ranged from 0.004 to 3.048%  
388 (Figure 3a), which is comparable to the ranges of %N found in Eastern US temperate forests by  
389 Serbin et al. (2014).

390 To predict LMA from the HSI data, we used a PLSR model with eight components. This  
391 model had an  $R^2$  of 0.72 for the training data, an  $R^2$  of 0.77 for the validation data, and an  $R^2$  of  
392 0.73 when applied to all the data (Table 1; Appendix S1: Fig.S5). All models had a p-value <  
393 0.001. Across the field measured samples, LMA values ranged from 20.72 to 326.02  $\text{g}/\text{mL}^2$ .  
394 After applying the PLSR coefficients to the images and removing extreme outliers using a  
395 Tukey's outlier test ( $k = 3$ ), LMA values ranged from 0.041 to 356.7  $\text{g}/\text{mL}^2$  (Figure 3b). While  
396 these values are extrapolated outside of the range of values used in our PLSR model, they are  
397 comparable to LMA ranges found globally by Poorter et al. (2009).

### 398 *3.2 Within Canopy Leaf Traits: Lidar and HSI*

399 To predict within canopy LMA, our final model consists of four lidar-derived metrics. These  
400 metrics included top of canopy %N, sample height, euphotic zone depth, and standard deviation  
401 of LAD within a column of voxels. Our final model for within canopy LMA had an  $R^2$  of 0.51  
402 for the training data and an  $R^2$  of 0.50 for our validation data (Appendix S1: Fig.S6). Both  
403 models had a p-value < 0.001.

404 After summing all within canopy values we calculated the total amount of N ( $\text{g}/\text{mG}^2$ ;  
405 Figure 4), foliar biomass ( $\text{g}/\text{mG}^2$ ; Figure 3d), and LAI ( $\text{mL}^2/\text{mG}^2$ ; Figure 3c) for each pixel. We  
406 then removed extreme outliers using Tukey's outlier test ( $k = 3$ ). Values greater than 15  $\text{g}/\text{mG}^2$   
407 were removed from the total canopy N raster (0.03% of raster pixels), values greater than 2465  
408  $\text{g}/\text{mG}^2$  were removed from the foliar biomass raster (0.46% of raster pixels), and values greater  
409 than 7  $\text{mL}^2/\text{mG}^2$  were removed from the LAI raster (0.03% of raster pixels).

410 To illustrate the differences in canopy profiles of within canopy N ( $\text{g}/\text{mG}^3$ ) we extracted  
411 data from the total canopy rasters using the GPS locations of a white oak (Figure 4a) and  
412 longleaf pine (Figure 4b) sample from our field data. The total amount of N in the white oak

413 sample was  $6.99 \text{ g/mG}^2$  while there was  $7.93 \text{ g/mG}^2$  in the canopy of the longleaf pine sample.  
414 Moreover, the profiles of each sample illustrate differing within canopy allocation strategies for  
415 the two species.

### 416 *3.3 Top of Canopy and Total Canopy N: Differing Spatial Patterns*

417 After normalizing (mean = 0, SD = 1) the top of canopy %N and total canopy N ( $\text{g/mG}^2$ ) rasters  
418 for equal comparison, there was no relationship between the two variables at any of the spatial  
419 resolutions, showing that these differences are not scale dependent (Figure 5, panels a, b, & c).  
420 Prior to normalization, we used linear regression to test the relationship between the two  
421 variables at each spatial resolution (Figure 5, panels d, e, & f). All linear regressions were  
422 significant ( $p\text{-value} < 0.05$ ), but the largest  $R^2$  value was 0.02 showing a very weak relationship  
423 between top of canopy and total canopy N across spatial resolutions. This lack of relationship  
424 shows that as data is aggregated together at coarser spatial resolutions, resulting in pixels  
425 containing multiple PFTs rather than single species, there are still distinct differences between  
426 top of canopy and total canopy N.

427 To assess differences in spatial patterns across the landscape, we calculated variograms  
428 for the top of canopy %N and total canopy N ( $\text{g/mG}^2$ ) datasets (Figure 6). A comparison of  
429 Moran's I values for the two normalized (mean = 0, SD = 1) datasets showed that the top of  
430 canopy %N map was substantially more spatially autocorrelated (Moran's I = 0.026) than the  
431 total canopy N map (Moran's I = 0.014). For the non-normalized datasets, top of canopy %N  
432 samples exhibit spatial autocorrelation up to a distance of 1200 meters, while total canopy N  
433 ( $\text{g/mG}^2$ ) samples are spatially autocorrelated up to a distance of 700 meters. Partial sill  
434 measurements also differ substantially, showing differences in variability between pairs of  
435 points, with top of canopy %N having a value of 0.23 and total canopy N ( $\text{g/mG}^2$ ) having a value

436 of 0.09. The shapes of the variograms indicate that top of canopy %N is grouped into clusters of  
437 similar values (lower nugget, longer range), while the total canopy N values are more evenly  
438 distributed (higher nugget, shorter range).

#### 439 *3.4 Regional Patterns and Environmental Drivers: Assessing Spatial Structure*

440 Elevation visually appeared to be a strong driver of leaf trait spatial distributions in our maps  
441 (Figure 3). To quantify this relationship, we looked at the influence of elevation on top of canopy  
442 %N, total canopy N ( $\text{g/m}_G^2$ ), and the normalized difference between these two datasets (Figure  
443 7). Top of canopy %N was related to elevation ( $R^2 = 0.13$ ), while total canopy N ( $\text{g/m}_G^2$ ) was not  
444 related to elevation ( $p > 0.05$ ). Therefore, the correlation between the normalized difference of  
445 these two estimates and elevation ( $R^2 = 0.06$ ) is mostly due to the stronger correlation between  
446 elevation and top of canopy %N.

447 To more broadly understand the effects of abiotic gradients and management regimes on  
448 leaf and canopy functional traits, we performed a Monte Carlo simulation on the abiotic and  
449 management rasters to compile a distribution of results. Models predicting top of canopy %N  
450 had a mean  $R^2$  of 0.24 with a standard deviation of 0.009. Eleven of the predictors appeared in  
451 over 20% of the models (Fig. 8), seven variables appeared in no models, and 7 variables  
452 appeared in all the models (Table 2). The only major topographic predictor (coefficient  $> 0.1$ )  
453 with a positive coefficient was soil wetness index (SWI), while major topographic predictors  
454 with a negative coefficient included elevation (DTM), solar radiation at the winter solstice  
455 (SR.WS), and TPI (topographic position index). The only major geologic predictor (coefficient  $>$   
456  $0.1$ ) with a negative coefficient was Coker substrate, while Eutaw substrate had a positive  
457 coefficient and was a major geologic predictor. The only major management variable (coefficient  
458  $> 0.1$ ) was areas burned in 2018 and it had a negative coefficient.

459 Total canopy N ( $\text{g}/\text{mG}^2$ ) models had a mean  $R^2$  of 0.03 with a standard deviation of 0.003.  
460 Eleven of the predictors appeared in over 20% of the models (Fig. 8), 4 variables appeared in no  
461 models and 2 variables appeared in all the models (Table 2). Solar radiation at the summer  
462 solstice was the only major topographic predictor (coefficient  $> 0.1$ ) with a negative coefficient,  
463 while the only major topographic predictor with a positive coefficient was distance from western  
464 collection boundary (easting). Alluvial substrate was the only major geologic predictor  
465 (coefficient  $> 0.1$ ) and it had a positive coefficient. There were no major management  
466 (coefficient  $> 0.1$ ) predictors in the total canopy regressions.

467 For both regression models many of the management variables appeared in only a small  
468 percentage of the total models. This is because these management practices were only completed  
469 across a small fraction of the entire landscape, and these areas were not randomly sampled in  
470 each iteration of the Monte Carlo simulation.

471 The residuals of both regression models exhibited some spatial autocorrelation with top  
472 of canopy %N having a mean Moran's I of 0.03 with a standard deviation of 0.001 and total  
473 canopy N ( $\text{g}/\text{mG}^2$ ) having a mean Moran's I of 0.008 with a standard deviation of 0.0006. While  
474 this spatial autocorrelation of the residuals would indicate that there is a trend present that we are  
475 not capturing, the aim of these regression was not predictive, but instead to compare the  
476 influence of these abiotic and management variables between the two functional traits estimates.

#### 477 **4. DISCUSSION**

478 We used airborne remote sensing and field-collected trait data to show that when three-  
479 dimensional forest structure is considered, different patterns of N appear across this landscape  
480 than are produced by two-dimensional top of canopy functional trait estimates. This analysis  
481 demonstrates that canopy functional diversity is not equivalent to leaf functional diversity, which

482 illustrates the dampened variation in total canopy N between PFTs and across this landscape  
483 when compared to the heterogeneous spatial patterns produced by leaf functional diversity. This  
484 suggests that these two measurements correspond to different ecological processes and that  
485 relationships between plant carbon assimilation and leaf functional traits must be considered in  
486 the context of canopy vertical structural heterogeneity.

#### 487 *4.1 Scaling and Mapping Leaf and Canopy Traits*

488 Many studies have used HSI data to estimate plant functional traits and lidar data to measure  
489 forest structure, with much success across a wide variety of ecoregions (Dahlin et al. 2013;  
490 Asner et al. 2015; Stark et al. 2015; Smith et al. 2019). By combining 3D structural traits from  
491 lidar and 2D functional traits from HSI, we show that a fusion of these two data types can be  
492 used to model traits within the canopy volume. Moreover, our findings are within the ranges  
493 reported in field-based studies for LAD (Parker and Tibbs, 2003; Brown and Parker, 2004), %N  
494 (Serbin et al. 2014), LMA ( $\text{g}/\text{mL}^2$ ; Poorter et al. 2009), and total canopy N ( $\text{g}/\text{mG}^2$ ; Cole and  
495 Rapp 1981; Fig. 9).

496 Our study focuses on an ecoregion consisting of closed-canopy broadleaf stands and  
497 sparser needleleaf forests, with our within-canopy trait estimates being reliable across these two  
498 plant functional types (PFTs). In addition, our within-canopy model utilizes variables related to  
499 the differences in PFTs (top of canopy %N), the local light environment (standard deviation of  
500 LAD within a column of voxels), and light capture (euphotic zone depth). These variables have  
501 been shown to be critical to canopy level processes (Field and Mooney 1986; Hardiman et al.  
502 2001; Lefsky et al. 1999).

503 While our results show that we can accurately model foliar functional traits within the  
504 canopy volume in this ecosystem, more research is needed in different biomes to test the ability  
505 of HSI and lidar to accurately estimate within-canopy traits.

#### 506 *4.2 Measuring Ecosystem Function: Top of Canopy %N vs. Total Canopy N*

507 While both foliar N and LMA have been identified as key drivers of plant functional diversity  
508 (Díaz et al. 2016) and have shown strong correlations with leaf photosynthesis in temperate  
509 ecosystems (Field and Mooney 1986; Evans 1989), we show that the spatial patterns of leaf-level  
510 top of canopy %N are not equivalent to those of total canopy N ( $\text{g/m}_G^2$ ). Top of canopy leaf-level  
511 traits reflect key differences between PFTs, with needleleaf species exhibiting low %N and high  
512 LMA, while broadleaf species have higher %N and lower LMA (Appendix S1: Fig.S1). These  
513 fundamental differences in functional and structural traits between PFTs produce distinct  
514 dendritic patterns across this landscape corresponding to topographic features including  
515 drainages, which are dominated by broadleaf species, and slopes and ridges, which are  
516 dominated by pines (Fig. 3a, b. c. & d). However, when three-dimensional canopy structure is  
517 considered (i.e. total canopy N), these distinct landscape patterns are dampened (Fig. 4).

518 Fig. 7 further shows that these distinct spatial patterns related to elevation are not  
519 reflected in our estimates of total canopy N ( $\text{g/m}_G^2$ ). This may suggest that canopy architectural  
520 differences between PFTs are causing unique distributions of N within the canopies of individual  
521 trees (Fig. 4a & b), and that these differences represent trade-offs since different PFTs exhibit  
522 similar total quantities of N ( $\text{g/m}_G^2$ ) in their canopies (Fig. 9). In this case, differences over a leaf  
523 function-structural architecture trade-off produces the dampened spatial patterns we see in this  
524 landscape (Fig. 4).

525           Given the importance of N for photosynthesis, these dampened spatial patterns may not  
526 be surprising. By varying LMA, individual trees will distribute N ( $\text{g/m}_L^2$ ) throughout their  
527 canopies in ways to maximize their nitrogen use efficiency, utilizing as much of the available N  
528 ( $\text{g/m}_G^2$ ) as possible. Lower total N ( $\text{g/m}_G^2$ ) within the canopy volume would imply lower  
529 production, a disadvantage that would be hard to reconcile between PFTs in the same ecosystem.  
530 While N-fixing trees could change these patterns, we observed no N-fixing trees in this  
531 landscape and overall, this area appears to have low N-fixing tree abundance (Staccone et al.  
532 2020).

### 533 *4.3 Abiotic and Management Drivers of Foliar and Canopy N*

534 Following community assembly theory (Keddy 1992), abiotic drivers have been shown to predict  
535 species and leaf trait distributions within landscapes with both remote sensing and field  
536 observations (Dahlin et al. 2012; Kraft et al. 2008). We show that these same types of drivers can  
537 be used to predict top of canopy %N in this system, but not total canopy N ( $\text{g/m}_G^2$ ).

538           Top of canopy %N patterns have consistently strong topographic, substrate, and  
539 management predictors, with many of these predictors being related to the distribution of PFTs  
540 across this landscape. For example, higher elevation areas that receive more solar radiation  
541 during the winter months and that were treated with a prescribed burn in 2018 prior to NEON  
542 AOP flights had consistently lower top of canopy %N values. This describes the spatial  
543 distribution of needleleaf species in this ecosystem. Conversely, lower elevation areas with a  
544 high soil water content had consistently higher top of canopy %N values, describing the  
545 distribution of broadleaf species in this environment. These relationships suggest that the spatial  
546 patterns of top of canopy %N are closely related to the spatial distribution of species within this  
547 ecosystem.

548 In contrast, variables related primarily to forest structural changes and water availability  
549 were the main drivers of total canopy N ( $\text{g}/\text{m}_G^2$ ), even though these relationships were  
550 considerably weaker, though still significant. For instance, areas that had been clear-cut, thinned,  
551 or burned had lower total canopy N ( $\text{g}/\text{m}_G^2$ ) estimates than areas that did not have a documented  
552 management history. This relationship is most likely due to management activities resulting in  
553 significant structural changes to forest stands and the removal of foliar biomass during these  
554 activities. Furthermore, areas that received high solar radiation in the summer months also had  
555 lower estimates of total canopy N ( $\text{g}/\text{m}_G^2$ ). This could be due to microclimatic effects. Water  
556 stress in these sunnier, drier areas may cause a reduction in growth and, therefore, total canopy N  
557 ( $\text{g}/\text{m}_G^2$ ), as light availability is not likely to be a limiting factor in this system.

#### 558 *4.4 Model Uncertainty and Data Concerns*

559 There are many possible sources of error and uncertainty to consider when scaling traits from  
560 leaf to landscape, including those related to field and GPS collections, laboratory equipment,  
561 remote sensing sensors, and statistical methodologies. While we did not conduct a formal  
562 assessment of uncertainty as it propagates through this study, our findings are within the ranges  
563 reported in many field-based studies (see section 4.1). Our final PLSR models did show a  
564 systematic bias of slightly underestimating N and LMA in needleleaf species (Appendix S1: Fig.  
565 S3 and Fig. S4), which could partially explain the differing landscape-scale relationships  
566 between total canopy and top of canopy N. This could possibly be improved by the inclusion of  
567 forest structure metrics such as LAI in the PLSR models. However, due to the low density lidar  
568 data we are forced to estimate structural traits at a coarser spatial resolution (10x10 meters) than  
569 the HSI data (1x1 meter). Because some field samples are closer than 10 meters to one another,  
570 and thus exist within the same pixel, the inclusion of structural traits did not correct this bias.

571 While understory shade tolerant plants play an important role in ecosystem functioning  
572 (Valladares et al. 2016), we ignored the lowest 10 meters of the forest canopy where many of  
573 these species occur due to limitations with the lidar data from the NEON AOP (Kamoske et al.  
574 2019). As current lidar sensors within the NEON AOP are upgraded, we will be able to ask  
575 important questions about the role of the understory in ecosystem functioning.

576 In this study we only considered healthy green forest vegetation, which may partially  
577 explain the weaker relationships between environmental variables and canopy functional and  
578 structural traits. More research is needed into how HSI and PLSR perform in stressed terrestrial  
579 environments and across more heterogeneous landscapes.

580 The development of a universal model to predict leaf- and canopy-level traits was beyond  
581 the scope of this project; however, as more within-canopy foliar traits are collected across a  
582 diversity of ecosystems, PFTs, and tree species, these models will become more robust and can  
583 be applied to other regions.

#### 584 *4.5 Looking Forward*

585 With airborne and spaceborne platforms like the NEON AOP, NASA Goddard's Lidar,  
586 Hyperspectral, & Thermal Imager (G-LiHT; Cook et al. 2013), the Global Ecosystem Dynamics  
587 Investigation (GEDI; Stavros et al. 2017), and the proposed Surface Biology and Geology  
588 Mission (SBG; National Academies of Sciences, Engineering, and Medicine 2018) collecting  
589 HSI and lidar data across a variety of ecoregions, there is a unique opportunity for researchers to  
590 ask and answer questions related to how forest canopies function across landscapes and  
591 continents, rather than just the leaves at the top of the canopy.

592 In support of these new questions about ecosystem function, we present a reproducible  
593 methodology to model foliar traits throughout the entire canopy volume. We also show that the

594 spatial patterns produced by traditional top of canopy measurements of %N are dramatically  
595 different than those produced when three-dimensional forest structure is considered. While more  
596 research is needed to test these relationships in different ecoregions and across latitudinal  
597 gradients, this ever-increasing availability of HSI and lidar data will provide new and exciting  
598 opportunities.

599         These opportunities may raise several questions about the drivers of canopy function. For  
600 example: A) What is the role of soil nutrient availability and heterogeneity in canopy function?  
601 and B) How are these relationships affected by latitudinal gradients and climate regimes? Further  
602 research is needed into these questions to better understand the drivers behind ecosystem  
603 functioning in horizontal and vertical space as well as through time.

## 604 **5. CONCLUSIONS**

605 Forest structural and functional diversity drive critical canopy processes related to carbon  
606 sequestration; however, structure and function are rarely considered in unison at ecosystem  
607 scales. Here we show that when forest structure is considered, the patterns produced by the total  
608 amount of N ( $\text{g}/\text{m}^2$ ) within the canopy volume are substantially different from the patterns  
609 produced by top of canopy %N. Furthermore, since total canopy N variation is dampened  
610 relative to leaf-level variation over a landscape characterized by variable PFT dominance, we  
611 find evidence of canopy architecture and leaf function tradeoffs. Patterns of total N are driven by  
612 different abiotic gradients and management regimes, further showing the differences between  
613 these two estimates of ecosystem function.

614         These differing spatial patterns, as well as differing abiotic and management drivers,  
615 show that canopy functional diversity is not equivalent to leaf functional diversity. By not  
616 considering structure and function together, there could be impacts on how we scale fine-

617 resolution ecological processes to landscape, continental, and global models. However, with new  
618 space- and airborne remote sensing platforms collecting HSI and lidar data across a variety of  
619 ecoregions, we have an opportunity to think about the terrestrial carbon cycle in three  
620 dimensions. This new approach will potentially unlock important insights into how forests  
621 function in a time of rapid anthropogenic and environmental change.

## 622 **6. ACKNOWLEDGMENTS**

623 Thanks to the Talladega National Forest - Oakmulgee Ranger District for providing site access,  
624 to NEON staff for providing technical support, and to O. Jain for providing assistance in the  
625 field. This work was supported in part by the NSF Macrosystem Biology Program award  
626 #1702379. The NEON is a program sponsored by the National Science Foundation and operated  
627 under cooperative agreement by Battelle Memorial Institute. This material is based in part upon  
628 work supported by the National Science Foundation through the NEON Program. Shawn P.  
629 Serbin was partially supported by the United States Department of Energy contract No. DE-  
630 SC0012704 to Brookhaven National Laboratory.

## 631 **7. DATA AVAILABILITY**

632 Lidar and HSI data are available at: <http://data.neonscience.org>. R package to estimate structural  
633 traits from airborne LiDAR data is provided through our GitHub at:  
634 <https://github.com/akamoske/canopyLazR> and as a stable DOI at  
635 <http://doi.org/10.5281/zenodo.3987340>. R package to pre-process HSI data, extract reflectance  
636 data, and apply PLSR coefficients is provided through our GitHub at:  
637 <https://github.com/akamoske/hypRSpec> and as a stable DOI at  
638 <https://zenodo.org/record/3987336>. Reflectance spectra and trait data are available through the  
639 ECOSIS database at: <https://data.ecosis.org/dataset/2018-talladega-national-forest--leaf-level->

640 reflectance-spectra-and-foliar-traits. Laboratory measured trait data are available through the  
641 TRY database (dataset ID = 714) at: [www.try-db.org](http://www.try-db.org).

965 Fig. 2. Workflow diagram showing our methodology for within canopy trait modeling. LAD =  
966 leaf area density ( $m_L^2/m_G^3$ ), LMA = leaf mass per area ( $g/m_L^{-2}$ ), N = foliar nitrogen content (g  
967 N/g leaf %), total canopy N = total canopy nitrogen content ( $g/m^2$ ). Field collected sunlit top of  
968 canopy %N & LMA refers to leaf samples that were collected at the top of the canopy, were  
969 constantly sunlit, and had no leaves above (i.e. no sun impediment). Field collected within  
970 canopy %N & LMA refer to leaf samples that were collected within the canopy (i.e. not  
971 constantly sunlit, shaded, and with other leaves surrounding them).

Fig. 9. North American Foliar N values vs. TALL Foliar N values. TC = Temperate Coniferous, TD = Temperate Deciduous. North American N (NA) values come from Cole and Rapp (1981). Because our values calculated at TALL do not include the lowest 10 meters of the canopy, ANOVA results ( $p < 0.001$ ) show a significant difference between NA and TALL values but not between Forest Types (TC and TD).

87 *Fig. S8. Top Figure shows the relationship between LAI derived from hemispherical*  
88 *photographs and raw LAI derived from lidar, used to calculate a Beer Lambert extinction*  
89 *coefficient ( $R^2 = 0.7181$ ). Bottom figure shows the relationship between Beer-Lambert adjusted*  
90 *LAI derived from lidar and LAI derived from hemispherical photographs ( $R^2 = 0.8629$ ). LAD is*  
91 *calculated as the following:*

92

93 *Within each voxel, LAD is estimated as:*

94 
$$LAD_{i-1,i} = \ln \left( \frac{S_e}{S_t} \right) \frac{1}{k\Delta z}$$

95 *where for each vertical column of voxels,  $i$  is a voxel in a sequentially ordered vertical column of*  
96 *the canopy,  $S_e$  is the number of pulses entering the given voxel,  $S_t$  is the number of pulses exiting*  
97 *the same voxel,  $k$  is an extinction coefficient, and  $z$  represents the height of a voxel. Together, the*  
98 *term  $1/k\Delta z$  represents a Beer-Lambert Law extinction coefficient, which relates reflectance and*  
99 *absorbance of light to the thickness and angle of a surface. Thus, as the canopy becomes denser*  
100 *and more leaves are encountered, the penetration of LiDAR pulses will diminish causing sample*  
101 *sizes for estimating LAD to decrease and error to increase.*
