22 Atmospheric Environment (January 2015)

19 **Abstract**

20 In this study the long-term trends of non-refractory submicrometer aerosol (NR-PM₁)
21 composition and mass concentration measured by an Aerosol Chemical Speciation Monitor
22 (ACSM) at the Atmospheric Radiation Measurements (ARM) program's Southern Great Plains
23 (SGP) site are discussed. NR-PM₁ data was recorded at ~30 minute intervals over a period of 19
24 months between November 2010 and June 2012. Positive Matrix Factorization (PMF) was
25 performed on the measured organic mass spectral matrix using a rolling window technique to
26 derive factors associated with distinct sources, evolution processes, and physiochemical
27 properties. The rolling window approach also allows us to capture the dynamic variations of the
28 chemical properties in the organic aerosol (OA) factors over time. Three OA factors were
29 obtained including two oxygenated OA (OOA) factors, differing in degrees of oxidation, and a
30 biomass burning OA (BBOA) factor. Back trajectory analyses were performed to investigate
31 possible sources of major NR-PM₁ species at the SGP site. Organics dominated NR-PM₁ mass
32 concentration for the majority of the study with the exception of winter, when ammonium nitrate
33 increases due to transport of precursor species from surrounding urban and agricultural areas and
34 also due to cooler temperatures. Sulfate mass concentrations have little seasonal variation with
35 mixed regional and local sources. In the spring BBOA emissions increase and are mainly
36 associated with local fires. Isoprene and carbon monoxide emission rates were obtained by the
37 Model of Emissions of Gases and Aerosols from Nature (MEGAN) and the 2011 U.S. National
38 Emissions Inventory to represent the spatial distribution of biogenic and anthropogenic sources,
39 respectively. The combined spatial distribution of isoprene emissions and air mass trajectories
40 suggest that biogenic emissions from the southeast contribute to SOA formation at the SGP site
41 during the summer.

44 trajectory analysis; Biomass burning

45 **1. Introduction**

46 Aerosols affect climate through scattering and absorption of radiation as well as influencing
47 the overall radiative properties, precipitation efficiency, thickness, and lifetime of clouds. As
48 described by the latest Intergovernmental Panel on Climate Change report (IPCC, 2014),

49 aerosols are one of the greatest sources of uncertainty in climate model predictions of radiative
50 forcing. The U.S. Department of Energy’s Atmospheric Radiation Measurement (ARM) program
51 was established in 1990 to collect measurements needed to provide a better understanding and
52 numerical representation of processes that affect atmospheric radiation in climate models (Stokes
53 and Schwartz, 1994). Long-term continuous measurements have been collected at the Southern
54 Great Plains (SGP) site near Lamont, Oklahoma since 1992; the Tropical Western Pacific (TWP)
55 site on Manus Island in 1996; Nauru Island in 1998; Darwin, Australia in 2002; and the North
56 Slope of Alaska (NSA) in Barrow, Alaska in 1997. The number and types of instruments
57 deployed at these sites have evolved over time. Today, the SGP site is the most comprehensive
58 climate research facility in the world with extensive in situ and remote sensing instrument
59 clusters deployed over about 143,000 km². Most of the instruments at the SGP site measure
60 radiation, cloud properties, and other meteorological quantities. Near-surface scattering and
61 absorption by aerosols at multiple wavelengths is obtained from nephelometers and Particle Soot
62 Absorption Photometers (PSAP), respectively (Sheridan et al., 2001), while the wavelength
63 dependence of aerosol optical depth (τ) within the atmospheric column above the SGP site is
64 obtained from sun photometers and MultiFilter Rotating Shadowband Radiometers (MFRSR)
65 (Kassianov et al., 2005). Other important aerosol optical properties, such as single scattering
66 albedo (ω_0), and asymmetry parameter, g , have been derived from the column MFRSR data.

67 Measurements of aerosol optical properties, such as τ , ω_0 , and g are very useful for
68 evaluating aerosol direct radiative forcing simulated by climate models. These quantities are also
69 available worldwide from NASA’s satellite and AEROSOL ROBOTIC NETWORK (AERONET)
70 measurements (Dubovik et al., 2002; Holben et al., 1998) and have been used by many model
71 evaluation and intercomparison studies, such as Aerosol Comparisons between Observations and
72 Models (AeroCOM). The first AeroCOM intercomparison (Kinne et al., 2006) found that
73 simulated τ was usually too low and that while the global averages were similar among the
74 models there were relatively large differences in the regional distribution of τ . They also showed
75 that there were large differences in simulated aerosol composition among the models. Myhre et
76 al. (2013) subsequently showed that these and other differences in the climate model treatments
77 contributed to a global mean aerosol direct radiative forcing that ranged from -0.58 to 0.02 W m⁻².
78

79 Fully understanding the sources of uncertainty contributing to this range of radiative forcing
80 estimates requires additional evaluation of predicted aerosol mass, composition, and size
81 distribution. While there have been few routine long-term measurements of these quantities
82 worldwide, global climate models are now more frequently being evaluated with whatever in situ
83 aerosol measurements are available. For example, Mann et al. (2014) recently evaluated the
84 simulated aerosol size distribution with new observational data and showed that while the
85 climate models qualitatively reproduced the observed mean size distributions, there were
86 relatively large errors in certain regions and seasons and some models performed better than
87 others. Spracklen et al. (2011) used a combined dataset of Aerosol Mass Spectrometer (AMS)
88 observations to optimize secondary organic aerosol (SOA) sources in a global aerosol
89 microphysics model – the Global Model of Aerosol Processes (GLOMAP) and verified the
90 optimized SOA predictions against Interagency Monitoring of Protected Visual Environment
91 (IMPROVE) network (Malm et al., 1994) measurements. Tsigaridis et al. (2014) focused on the
92 performance of simulated organic aerosol (OA) among global models and found that increased
93 complexity in the treatment of OA did not necessarily lead to improved results. In addition, the
94 range of OA predictions widened in recent climate models compared to the previous AeroCOM
95 intercomparison described by Kinne et al. (2006) because of the differences in the treatment of
96 OA and the addition of highly uncertain OA precursor sources. One of these models, DOE’s
97 Community Atmosphere Model version 5 (CAM5), contains a more detailed treatment of the
98 aerosol lifecycle than in the previous version (Liu et al., 2012), but simulated near surface OA
99 was found to be too high when compared with IMPROVE network data over North America.

100 These studies demonstrate that co-located measurements of meteorology, radiation, and
101 aerosols are needed to evaluate treatments of aerosol processes in climate models. Measurements
102 characterizing chemical and physical properties of aerosols are important for understanding
103 sources and processes of aerosols in the atmosphere, and can also be used to predict aerosol
104 optical and hygroscopic properties. At the ARM SGP site, various instruments have been
105 deployed over the years to measure aerosol size distribution, including most recently a Tandem
106 Differential Mobility Analyzer (TDMA) and Aerosol Particle Sizer (APS). While daily filter
107 samples of aerosols were collected between 2000 and 2008, more detailed and routine
108 measurements of aerosol composition were not available until recently. An Aerosol Chemical
109 Speciation Monitor (ACSM) (Ng et al., 2011b) has been deployed at the SGP Central Facility

110 since late 2010 to measure temporal variations in non-refractory submicron particulate matter
111 (NR-PM₁) including OA, sulfate (SO₄²⁻), nitrate (NO₃⁻), ammonium (NH₄⁺), and chloride (Cl⁻).
112 The ACSM is similar to the Aerosol Mass Spectrometer (AMS) that has been widely used to
113 obtain aerosol composition measurements during field campaigns conducted throughout the
114 world (Jimenez et al., 2009; Zhang et al., 2007a), except that it cannot measure particle size and
115 is lower in cost, size, and weight. The lower cost of the ACSM also means lower sensitivity, thus
116 less time resolution, when compared to the AMS, but the ACSM is better suited for long-term
117 routine monitoring and thus provides information needed to evaluate the seasonal and yearly
118 variability of aerosols simulated by climate models. For example, Sun et al. (2012) deployed an
119 ACSM in Beijing, China to characterize organic and inorganic aerosols during the summer to
120 understand high PM pollution events. Tiitta et al. (2014) describe the variation in aerosol
121 composition measured by the ACSM over a one-year period in South Africa and quantify
122 significant differences in aerosol mass and composition between the wet and dry seasons. In
123 addition, Carbone et al. (2013) describe urban aerosol composition measured with the ACSM in
124 Santiago de Chile over a period of three months.

125 In this study we analyze the ACSM measurements collected at the SGP site and quantify the
126 diurnal, weekly, monthly, and seasonal variations in OA, sulfate, nitrate, ammonium, and
127 chloride over 19 months. Positive Matrix Factorization (PMF) analysis of the organic mass
128 spectra was performed using a 2-week rolling window algorithm to determine the OA factors and
129 their variations over time. An analysis of back trajectories is used to illustrate potential sources
130 of aerosols and aerosol precursors transported to the SGP site. The routine NR-PM₁ composition
131 measurements at SGP will enable climate modelers to better identify the sources of uncertainties
132 in aerosol radiative forcing simulations, when coupled to the existing extensive meteorological,
133 radiation, aerosol optical property, and size distribution measurements. While there are routine
134 aerosol composition measurements collected over the U.S. (e.g. IMPROVE network), they
135 consist of averages over one-day or multi-day periods and those sites lack the detailed coincident
136 measurements of radiation, aerosol optical properties, meteorology, and clouds needed to
137 evaluate the factors contributing to aerosol radiative forcing. Compared to filter sampling, the
138 ACSM will provide more detailed chemical speciation information with higher time resolution
139 (< 1 hr) that can capture the dynamic variations of aerosol chemistry. Measurements of

140 atmospheric constituent at hourly or shorter time resolution are important for validating
141 photochemical aerosol Chemical Transport Models (CTMs) (Wexler and Johnston, 2008).

142 **2. Experimental Methods**

143 **2.1. SGP Site Description and ACSM Measurements**

144 The location of the ACSM instrument deployed at the Central Facility of the ARM SGP site
145 in north-central Oklahoma is shown in Figure S1 in the Supplementary Material. The land use in
146 the vicinity of the Central Facility is rural and is composed of mixed farming (pasture, wheat,
147 alfalfa, soybeans) and grassland. The nearest metropolitan areas are Wichita (population ~0.7
148 million) located ~110 km to the north, Oklahoma City (population ~1.3 million) located ~135
149 km to the south, and Tulsa (population ~1.1 million) located ~150 km to the southeast. Smaller
150 cities such as Enid (population ~50,000), Stillwater (population ~47,000), and Ponca City
151 (population ~25,000) are located 43 km to the south, 77 km to the southeast, and 42 km to the
152 east of the Central Facility, respectively. ACSM measurements have been collected at ~30 min
153 intervals since late 2010 and this analysis covers data from November 2010 through July 2012.

154 The ACSM sampled ambient air with a total flow rate of 3 L min⁻¹. The sample stream to the
155 ACSM was dried with a Nafion dryer to avoid water condensation in the sampling line, which
156 can influence collection efficiency (CE) of particles (Middlebrook et al., 2012). The ACSM
157 measures the chemical composition of NR-PM₁. Detailed descriptions of the ACSM operating
158 principles and calibration procedures are available elsewhere (Ng et al., 2011b). Briefly particles
159 enter an aerodynamic lens through a critical orifice of 100 μm diameter at a rate of 0.1 L min⁻¹
160 under vacuum. This focused particle beam impacts and vaporizes on a hot oven (~600°C),
161 ionizes with 70eV electrons, and the resulting ions are detected using quadrupole mass
162 spectrometry. Particle and background signals are differentiated using a 3-way valve automated
163 switching system, which switches sample flow between ambient and particle-free air. More
164 details on ACSM calibration and corrections can be found in the Supplementary Section 1.

165 **2.2. Organic Aerosol Component Value-Added Product**

166 Organic aerosols make up a large fraction of total NR-PM₁ mass (Zhang et al., 2007a) and
167 can influence the radiative forcing of aerosols. Therefore it is important to study the chemical
168 and physical properties of OA. The OA measured by the ACSM was investigated using the

169 Organic Aerosol Component (OACOMP) value-added product (VAP)
170 (www.arm.gov/data/vaps). This VAP was developed to determine the sources and chemical
171 evolution of OA from long term and continuously expanding ACSM datasets. The VAP can be
172 described as a rolling window analysis that performs PMF (Paatero and Tapper, 1994) on long-
173 term data in user-defined intervals. The procedure for the OACOMP VAP is discussed in detail
174 in the Supplementary Section 2, and a brief explanation is given here. For this study PMF was
175 performed on every 2 weeks of data, incrementing by 1 day, until the end of the data was
176 reached. For every PMF analysis an OA ensemble mass spectral matrix and a measurement error
177 matrix are calculated for a two-week period according to Ulbrich et al. (2009). Note that analysis
178 of 2-weeks of data was chosen because this length captures the variations of aerosols and is
179 representative of the average lifecycle of aerosols in the atmosphere (see Supplementary Section
180 2.1). Pretreatment is then applied to both matrices following the procedures given in Zhang et al.
181 (2011). Specifically, problematic m/z 's ($S/N < 0.2$) were downweighted by a factor of 20 and
182 weak m/z 's ($0.2 > S/N > 2.0$) were downweighted by a factor of 2. A minimum error of $1 \times 10^{-2} \mu\text{g}$
183 m^{-3} was applied to the error matrix. Finally m/z 's 44, 18, 17, and 16 were downweighted by a
184 factor of 2 because of the association of the latter 3 ions with m/z 44 in the organic fragmentation
185 table. The PMF code is run on the two pretreated matrices to produce two to three factors using
186 $\text{FPEAK} = 0.0$. The code allows for the possibility of 3 factors, including a BBOA factor and two
187 types of OOA factors. No hydrocarbon-like factor is extractable in this dataset, which is
188 consistent with the rural characteristics of the SGP site. A BBOA factor is identified if one factor
189 has f_{60} (i.e., fraction of total signal at $m/z = 60$) greater than or equal to 0.008. The two OOA
190 factors are differentiated several ways, the first is based on f_{44} values, where the factor with
191 greater f_{44} is identified as OOA-1 and the other as OOA-2. As factor profiles are produced OOA
192 factors are also differentiated by comparing time series with previously adjacent time series in
193 the rolling window analysis. Additional evidence to support the identification of each factor
194 includes time series correlation with tracer species, diurnal variations in mass concentration, and
195 characteristic mass spectral peaks. A more thorough description of the identification of factors is
196 given in 3.2. The average time series can be found in the supplementary section (Fig. S3a-c) and
197 the average mass spectrum of each factor obtained from the VAP are reported in Fig. 3a-c.

198 When used on long-term data the VAP results give insight into the variations of OA factors
199 with respect to time of year and also quantify the uncertainties for each of the factors from PMF.

200 The main outputs of the VAP are mass spectra and mass concentration time series of OA factors
201 that are representative of key sources, atmospheric formation and evolution processes, and
202 physiochemical properties of OA (Zhang et al., 2011). Since the sum of all OA factors represents
203 the total OA mass, these results are important for evaluating model predictions of sources and
204 processes that contribute to total OA and also for closure studies on aerosol optical and cloud
205 condensation properties. A better understanding of OA factors in the atmosphere from these
206 results will also improve the representation of OA in models and help to reduce uncertainty
207 associated with direct and indirect forcing of aerosols in climate models.

208 **2.3. Back trajectory analyses**

209 To illustrate the transport pathways and potential sources of aerosols observed at the SGP
210 site, back trajectories were computed using the Hybrid Single-Particle Lagrangian Integrated
211 Trajectory (HYSPLIT) model (Draxler and Rolph, 2013). Seven-day back trajectories were
212 computed every three hours during the same time period as the ACSM measurements based on
213 the large-scale meteorological fields available from the National Oceanic and Atmospheric
214 Administration (NOAA) Global Data Assimilation System (GDAS). The horizontal spatial grid
215 spacing of GDAS is 1 degree. All of the back trajectories originated 10 m above the ground at
216 the SGP Central Facility and vertical transport was based on the mean vertical velocities from
217 GDAS.

218 **3. Results and Discussions**

219 **3.1. An overview of the variations in air mass trajectories**

220 The seasonal variations in air mass transport to the SGP during 2011 based on HYSPLIT is
221 shown in Figure 1 where the warmer colors denote higher frequently occurrence of back
222 trajectory positions during each 3-month period. During the winter, northerly winds occur a
223 larger fraction of time along with recirculating air masses over the south-central U.S. (Fig. 1a
224 and 1e). Not surprisingly, transport to the SGP during the spring transition months is from both
225 the south and north (Fig. 1b and 1f) that depends on position of high and low pressure systems
226 passing through the region. Southerly winds dominate during the summer so that aerosols and
227 their precursors are likely transported from Oklahoma and eastern Texas (Fig. 1c). The shorter
228 back trajectories are due to wind speeds that are generally lower during the summer. The

229 transport pathways during the fall (Fig. 1d) were similar to those during the spring, except that
230 there was less transport over southeastern Texas. This analysis also shows that air masses are
231 unlikely to pass over the eastern and southwestern U.S. over the seven-day trajectory intervals. It
232 is possible that air masses from the southeastern U.S. can be transported over the SGP site, but
233 the transport period would be much longer than seven days. Note that back trajectories starting at
234 higher altitudes where the wind speeds are higher would be longer than those shown in Figure 1;
235 however, air masses would need to arrive over the SGP site at or below the top of the boundary
236 layer.

237 The carbon monoxide (CO) emission rates from the 2011 National Emission Inventory and
238 the emission rates for isoprene computed by the Model of Emissions of Gases and Aerosols from
239 Nature (MEGAN) (Guenther et al., 2006) are shown in Figures 1g and 1h, respectively, for
240 reference. The CO emissions represent the spatial distribution of anthropogenic sources, while
241 the isoprene emissions represent the spatial distribution of biogenic sources. The isoprene
242 emission rates are from a typical summer day, so the rates would be much lower during the
243 winter. The high frequency of southerly winds suggests that Tulsa, Oklahoma City, and the
244 Dallas-Fort Worth area likely contribute anthropogenic aerosol and aerosol precursors at the SGP
245 site throughout the year. However these cities are 100 km or more from the SGP site so that
246 dilution will reduce their concentrations before arriving at the SGP site. A large number of the
247 trajectories pass during the summer over the high isoprene emissions regions east and southeast
248 of the SGP site (Fig. 1c). This suggests that biogenic emissions likely contribute SOA mass at
249 SGP primarily during the summer. Additional analysis relating observed biomass burning
250 aerosol and inorganic aerosol species with the back trajectories is discussed in Section 3.4.

251 **3.2. Temporal variations of submicron aerosol mass loading and composition**

252 From November 20, 2010 to June 28, 2012 the temporal variations in meteorological
253 conditions and NR-PM₁ particle composition and mass concentration at the SGP site are
254 summarized in Figure 2.

255 The average ($\pm 1\sigma$) mass concentration of total NR-PM₁ over the entire dataset is 7.0 (± 9.3)
256 $\mu\text{g m}^{-3}$. A summary of the mass concentrations of major NR-PM₁ species for the entire study is
257 shown in Table 1 and in Fig. S5. For the majority of the study, the molar equivalent ratios of
258 ammonium to anions (i.e., nitrate, sulfate, and chloride) measured by the ACSM were calculated
259 to be near 1, indicating that particles are fully neutralized and that inorganics are predominantly

260 in the forms of NH_4NO_3 , $(\text{NH}_4)_2\text{SO}_4$, and NH_4Cl (Zhang et al., 2007b). As shown in Fig. 2c, the
261 total NR- PM_{10} mass concentration has a large range with substantially enhanced mass
262 concentrations between February – May 2011 and February – March 2012. These spikes in NR-
263 PM_{10} are associated with increases in ammonium nitrate and the 2011 spikes are also associated
264 with biomass burning emissions (Fig. 2d). This observation is consistent with the fact that
265 prescribed agricultural burning in the region commonly occurs during spring months in
266 preparation for crops (Reid et al., 2004).

267 Note that the time series of NR- PM_{10} mass concentrations measured by the ACSM and PM_{10}
268 volume concentrations measured by a Tandem Differential Mobility Analyzer (TDMA) show
269 similar trends (Fig. S4). However, the linear regression slope for comparing mass and volume
270 measurements for the entire study period is $\sim 2.7 \text{ g cm}^{-3}$, much higher than the average ($\pm 1\sigma$)
271 density (ρ) of NR- PM_{10} ($1.40 \pm 0.09 \text{ g cm}^{-3}$; Fig. 2b) estimated based on measured NR- PM_{10}
272 composition assuming that the densities of inorganics and organics are ~ 1.72 and $\sim 1.2 \text{ g cm}^{-3}$,
273 respectively. A possible reason for this discrepancy could be that different particle sizes are
274 measured by the TDMA (12 – 712 nm) and ACSM ($\sim 30\%$ transmission efficiency at $1 \mu\text{m}$ (Liu
275 et al., 2007)). Comparisons of mass measured by the ACSM with filter measurements are not
276 possible given that filter measurements at SGP were taken only for 2000-2007 and IMPROVE
277 measurements do not cover the dates of this study. Furthermore we show seasonal differences in
278 NR- PM_{10} composition may be due to meteorological variations, thus comparing previous filter
279 measurements with this dataset could be problematic.

280 From the VAP analysis of the OA dataset three factors were obtained including two types of
281 OOA factors, where one is more oxidized with a higher f_{44} (i.e., fraction of total signal at $m/z =$
282 44) than the other, and a biomass burning OA (BBOA) factor (Fig. 3). In order to test the overall
283 performance of PMF, organic mass concentration was reconstructed from the three OA mass
284 concentrations and correlated with the measured organic concentration from the ACSM (Fig.
285 S6). From the linear regression it was determined that the approximated and measured organic
286 mass are in good agreement with a linear regression slope of 1.004, intercept of 0.042, and $r^2 =$
287 0.987. The average mass spectra of the two OOA factors (Fig. 3a-b) show that f_{44} is higher for
288 OOA-1 than OOA-2, and the fraction of total signal at $m/z = 43$ (f_{43}) is higher for OOA-2 than
289 OOA-1. The ion signal at $m/z = 44$ commonly comes from the thermal decomposition of
290 carboxylic acids on the vaporizer resulting in a CO_2^+ peak (Alfarra et al., 2004). The signal at

291 $m/z = 43$ mainly comes from the fragmentation of hydrocarbon chains to form $C_3H_7^+$ and
292 carbonyls to form $C_2H_3O^+$. Therefore OOA-1 is representative of more-oxidized OA and OOA-2
293 is representative of less-oxidized OA. BBOA is a surrogate for OA emitted from biomass
294 burning and has significant mass spectral peaks at $m/z = 60$ and 73 , which are associated with
295 anhydrous sugar such as levoglucosan emitted from wood burning (Alfarra et al., 2007;
296 Schneider et al., 2006). BBOA mass concentration increases sporadically throughout the year but
297 the majority of BBOA occurs during spring (41% of the days with BBOA influence) and winter
298 (38%) and less frequently during summer (11%) and fall (9%). It is common to identify OOA
299 types based on significant mass spectral peaks as well as mass concentration time series
300 correlation with tracer species. In addition to having a large signal at $m/z = 60$, the BBOA factor
301 also correlates well with the $m/z=60$ time series (Fig. S3c). Figure S7 shows the scatter plots of
302 the OOA factors with secondary inorganic species colored by ambient temperature. OOA tends
303 to have a temperature dependent correlation with nitrate such that the slope increases as
304 temperature increases. Unlike nitrate, neither OOA factors nor sulfate concentrations are
305 dramatically influenced by temperature (Fig. S8). The total OOA concentration correlates well
306 with the sum of secondary inorganic (nitrate and sulfate) concentrations with similar temperature
307 dependence discussed previously, thus supporting the secondary nature of OOA and the notion
308 that OOA in this study likely consists of low-volatility species.

309 In Figure 4a is a triangle plot of organic f_{43} versus f_{44} for the entire dataset along with the
310 range in f_{43} and f_{44} values for the three PMF factors obtained from the VAP analysis. The dotted
311 lines represent the typical f_{43} and f_{44} bounds for OA factors found in previous global studies (Ng
312 et al., 2010). Also shown in Fig. 4a and 4b are f_{44} , f_{43} , and f_{60} values from previous studies,
313 including standard semi-volatile (SV-OOA) and low-volatility oxidized OA (LV-OOA) (Ng et
314 al., 2011a); factors from Pasadena, CA (Hersey et al., 2011); Paris, FRA (Crippa et al., 2013);
315 Zurich, CHE (Lanz et al., 2007); Fresno, CA (Ge et al., 2012b); and lab studies
316 (<http://cires.colorado.edu/jimenez-group/AMSsd/>). OOA-1 is located near the apex of the
317 triangle and is representative of highly aged and oxidized OA. OOA-2 is less oxidized than
318 OOA-1 but is more oxidized than previously found SV-OOA factors that have lower f_{44} values.
319 BBOA is the least oxidized OA of all the PMF factors found in this study. The box plots show
320 the large range in oxidation for each OA factor and emphasize that constant factor profile mass
321 spectra do not fully capture the dynamic variations of long-term datasets (more discussion in

322 Supplementary Section 3). Figure 4b shows that BBOA is within the range of f_{60} and f_{44} values
323 found in previous ambient studies and the two OOA factors are distinct from the BBOA factor.
324 Overall OA seems to be highly oxidized for most of the study such that the majority of data
325 points are located near the apex of the triangle (OA have high f_{44} and low f_{43} values). An
326 exception to this occurs during biomass burning events when f_{60} is high, OA is less oxidized, and
327 elevated concentrations occur. This tendency for OA to be highly oxidized is consistent with the
328 previous discussion that OOA consists mostly of low-volatility species.

329 **3.3. Monthly, seasonal and diurnal variations of aerosol composition**

330 It is difficult to see immediate trends in this long-term dataset and as a result it is useful to
331 look at monthly, seasonal, and diurnal trends in aerosol composition and mass concentrations.
332 Anthropogenic influences on NR-PM₁ chemistry were also investigated (see Supplementary
333 Section 4). The major results from the 2011 dataset (Jan. – Dec. 2011) are summarized in Figure
334 5 to give insight into aerosol composition and concentration changes over the course of one year.
335 This wheel plot shows how the NR-PM₁ composition, average concentration, OA composition,
336 and wind change on a monthly basis. The largest average mass concentration in NR-PM₁ occurs
337 between January – April due to a combination of lower atmospheric boundary layer (ABL)
338 height, enhanced emissions of BBOA, and lower temperature that promotes the condensation of
339 semi-volatile species such as ammonium nitrate and semi-volatile organic species (section 3.4).
340 As ambient temperatures increase from May to August semi-volatile species decrease due to
341 partitioning into the gas-phase. Overall the highest NR-PM₁ mass concentrations occur at the
342 beginning of 2011 and decrease as the year progresses.

343 For the entire dataset (Nov. 2010 – June 2012) seasonal wind data and average mass
344 concentrations and composition of NR-PM₁ are summarized in Figure 6. The highest NR-PM₁
345 mass concentration occurs in the winter of 2010-2011 and decreases from the spring to fall of
346 2011. Similar seasonal patterns are seen for 2012, such that beginning in the winter of 2011-2012
347 concentrations increase then decline in the following seasons. Therefore the cyclic nature of NR-
348 PM₁ mass concentrations seen for 2011 (Fig. 5), where peak concentrations occur in the winter
349 and decrease as the year progresses is also seen for the first half of 2012. The composition of
350 NR-PM₁ is very similar among the same seasons, such that nitrate dominates NR-PM₁ mass
351 concentration in both winters. All other seasons have organics contributing the most to total NR-
352 PM₁ mass concentration. Changes in OA factor profiles with season were investigated for OOA-

353 1, OOA-2, and BBOA (Fig. S10) and more discussion can be found in the Supplementary
354 Section 3.

355 The diurnal variations of major NR-PM₁ species concentration, temperature, and relative
356 humidity separated by season are shown in Figures 7, S11, and S12. Most species lack distinct
357 diurnal variations with the exception of nitrate. Aerosol nitrate is formed from the precursor gas
358 HNO₃. The formation of HNO₃ can occur several ways including daytime reaction of NO₂ and
359 OH radical and various nighttime reactions involving NO₃ radical and N₂O₅ (Seinfeld and
360 Pandis, 2006). Two main diurnal patterns for nitrate are observed during this study that may be
361 indicative of daytime and nighttime formation of HNO₃. Kim et al. (2014) have recently
362 observed that daytime production of HNO₃ corresponds to a peak in total nitrate (HNO₃ + NO₃⁻)
363 production rate around late afternoon in the Northern US during winter. They also found that
364 when nighttime production of HNO₃ is dominant, the total nitrate production rate peaks in the
365 early morning and at night. Following this logic, at SGP during winter 2010-11 and spring 2011
366 the diurnal patterns of nitrate may be associated with nighttime production of HNO₃ whereas
367 photochemical production of HNO₃ is likely responsible for the nitrate peaks in the mid-
368 afternoon during fall 2011 and spring 2012. For the summer of 2011 nitrate concentrations are
369 low and lack a strong diurnal variation. This diurnal pattern might be due to the abundance of
370 nitrate in the form of organonitrates, which are less volatile and therefore less temperature
371 dependent than more volatile species like ammonium nitrate (Perraud et al., 2012). Enhanced
372 ratio of $m/z = 30$ to $m/z = 46$ provides evidence for organonitrates (Farmer et al., 2010). The
373 average m/z 30:46 ratio for summer 2011 is ~10, substantially higher than the ratio for
374 ammonium nitrate determined during ionization efficiency calibrations. This flat diurnal pattern
375 for nitrate could also be related to competitive processes of nitrate production and evaporative
376 loss during the daytime. Simultaneous measurements of nitric acid and ammonia would be
377 needed to fully understand nitrate fluctuations. In addition to nitrate having a distinct diurnal
378 pattern, BBOA in the spring shows enhanced concentrations during the early morning and
379 throughout the evening, and suspected to be related to variability in ABL height.

380 With more than one year of data, the aerosol chemistry of overlapping seasons was
381 compared, which for this dataset includes two winters (2010-11 and 2011-12) and two springs
382 (2011 and 2012). The total NR-PM₁ concentration is greater for winter 2010-11 than winter
383 2011-12, mainly due to substantially higher concentrations of inorganic species, especially

384 nitrate (Fig. 6). The average concentrations of all aerosol species are much higher during spring
385 2011 than spring 2012 (Fig. 6), for which somewhat different source influences between the two
386 years could be partly responsible. For example, according to the wind roses, the SGP site is
387 subjected to more NW and NE winds in spring 2011 compared to spring 2012. Fire records also
388 indicate that BB emissions during March 2012 are ~17% less than March 2011, and wind
389 directions are not favorable to transport BB emissions to the site during March 2012 (Fig. S13).

390 In addition, winter 2010-11 and spring 2011 are overall colder and drier than winter 2011-12
391 and spring 2012, respectively (Fig. 7). Less influence of wet deposition might be a reason that
392 both winter 2010-11 and spring 2011 have higher total NR-PM₁, whereas colder temperatures
393 and more photochemical activities in winter 2011-12 and spring 2011 compared to the following
394 winter and spring, respectively, might explain the higher fraction of nitrate in NR-PM₁ (Fig. 6).
395 In addition, the fact that winter 2011-12 and spring 2012 have higher fractions of OOA-1
396 compared to winter 2010-11 and spring 2011 (Fig. 6) might be due to more humid conditions
397 that facilitate aqueous phase processing (Ge et al., 2012a).

398 **3.4. Sources of NR-PM₁**

399 As shown in Figure 5, there is a substantial amount of BBOA present at the SGP site during
400 February, March, and April of 2011. To better understand how smoke is transported to the SGP
401 site, Figure 8 compares the temporal variations of BBOA with variations in fire locations and
402 daily organic carbon (OC) emission rates from the Fire INventory from NCAR (Wiedinmyer et
403 al., 2011) as well as back trajectories. As shown in Figure 8a, the high OC emissions within ~5
404 degrees (light gray shading) and ~2.5 degrees (dark gray shading) of the SGP site occur most
405 frequently during March and April, corresponding to the highest overall monthly BBOA
406 concentrations (Figures 5 and 8b). To examine the temporal variations in more detail, the daily
407 OC emission rates and BBOA for March are shown in Figures 8c and 8d, respectively. Peak
408 BBOA concentrations usually occur one to two days after high OC fire emissions. The exception
409 is March 10-12 when BBOA is relatively low and fires with relatively higher emissions similar
410 in magnitude to other events during the month occur southeast of the SGP site; however, most of
411 the back trajectories show air masses at the SGP site on those days did not pass over those fires
412 (not shown). As shown in Figure 8e, fires with the highest emission rates within 5 degrees of the
413 SGP site occur in southeastern Oklahoma and western Arkansas, but the back trajectories (Figure
414 8g) suggest that a portion of the smoke during March could have originated from a large number

415 of smaller fires closer to the SGP site. In contrast, the number of fires during July 2011 was
416 much less (Fig. 8f). While there were a few fires north of the SGP site, all of the back trajectories
417 show transport from the south (Fig. 8h). The direction of those trajectories indicate that transport
418 from the larger fires in the southeastern U.S. was possible, but the transport period was greater
419 than 7 days so that any smoke originating from those fires are very dilute by the time they arrive
420 at the SGP. The PMF approach is not able to identify very low concentrations of BBOA if they
421 were present. In general, the BBOA at the SGP site is consistent with fire emission inventory and
422 suggest that local fires contributed to the higher BBOA concentrations during the spring of 2011.
423 Additional analyses using a chemical transport model would be needed to identify the relative
424 contribution of each fire to the BBOA at the SGP site as well as to quantify the relative
425 contribution of local and distant sources.

426 Figure 9 presents an analysis of temporal inorganic aerosol variations between January and
427 March 2011 in relation to the spatial variations of ammonia, NO_x , and sulfur dioxide (SO_2)
428 emissions and select back trajectories. Nitrate concentrations at SGP are highest during the
429 winter months, with peak daily-averaged values exceeding $10 \mu\text{g m}^{-3}$ on 21 days between
430 January and March 2011 (Fig. 9a), and multi-day variations in ammonium and nitrate are well
431 correlated with each other. The coldest temperatures occur mostly in January and early February,
432 with shorter periods of cold temperatures during March (Fig. 9b). It is evident that all of the high
433 nitrate episodes are associated with temperatures below 3°C (Fig. 9a). At warmer temperatures
434 nitrate quickly partitions back to the gas phase, decreasing nitrate concentrations. The sources of
435 nitrogen from surface ammonia and NO_x emissions are shown in Figures 9c and 9d, respectively.
436 A significant amount of NO_x is also emitted from numerous power plants (not shown).
437 Relatively low emission rates of both NH_3 and NO_x occur in the immediate vicinity of the SGP
438 site and higher emission rates are located several hundred kilometers or more away. The back
439 trajectories associated with nitrate $> 10 \mu\text{g m}^{-3}$ (Fig. 9e) pass over different ammonia and NO_x
440 emission sources in all directions prior to arriving at the SGP site. A similar analysis of the back
441 trajectories associated with nitrate $> 3 \mu\text{g m}^{-3}$ for January, February, and March are shown in
442 Figures 9f, 9g, and 9h, respectively. During January when the temperatures are the coldest
443 overall, back trajectories are primarily from the north to northwest and pass over the relatively
444 higher ammonia emissions in Nebraska (Fig. 9f). During February (Fig. 9g), the transport
445 pathways are similar to January except there are a few days in which transport is from the south

446 suggesting that NO_x sources from Oklahoma City and Dallas-Fort Worth may have contributed
447 to nitrate. Transport from the south becomes more frequent during early spring in March (Fig.
448 9h). Thus, the relative contribution of ammonia and NO_x on nitrate likely depends on the
449 ambient winds and the emission rates upwind are sufficiently high to produce nitrate
450 concentrations as long as the temperature is sufficiently low.

451 In contrast with other rural areas of the world (Zhang et al., 2011) (e.g., sulfate accounts for
452 an average ~39% of total NR-PM₁ concentration), sulfate at the SGP site is a relatively lower
453 fraction of the total aerosol concentrations. As shown in Figure 2d, sulfate concentrations exceed
454 2 μg m⁻³ on 82 days between January and June, but concentrations are much lower for the
455 remainder of the year. Nevertheless, the fraction of sulfate to the total aerosol concentration
456 changes little during the year (Fig. 6). Temporal variations in sulfate for January through March
457 are shown in Figure 9i in relation to the variations of nitrate and ammonium. Sulfate is not
458 correlated with temperature because of its longer lifetime (Fig. S7). There are numerous point
459 sources of sulfur dioxide (SO₂) surrounding the SGP site with many small emission sources (<
460 10⁻⁵ ton day⁻¹) and fewer locations where emissions exceed 0.1 ton day⁻¹ (Fig. 9j – 9l). Area
461 sources of sulfur dioxide are not shown since they are much smaller than the point sources.
462 During January (Fig. 9j), the peaks in sulfate concentrations are likely from three large sulfur
463 dioxide emission sources close to the SGP site, one located a few kilometers southwest of the
464 SGP site, one in south-central Kansas, and the other close to Oklahoma City. During February
465 (Fig. 9k), the trajectories indicate a more broad distribution of SO₂ sources located southwest,
466 south, and southeast of the SGP site in Oklahoma contribute to peak sulfate concentrations. In
467 contrast, peak sulfate concentrations are mostly associated with transport by northeasterly winds
468 from SO₂ sources in southeastern Kansas during March (Fig. 9l). There are still a few periods in
469 which transport is from other directions. The locations of the SO₂ sources and the variable winds
470 at the SGP site suggest that many sources can contribute to sulfate at the SGP site. The closest
471 SO₂ sources with the highest emission rates may not be the biggest contributors to the overall
472 sulfate concentrations during much of the year. The higher sulfate concentrations during the
473 winter months are also due to lower boundary layer depths that inhibit vertical mixing. This
474 simple analysis cannot point to the role of aqueous chemistry in clouds that could enhance
475 sulfate over transport periods of many days.

476 While the back trajectories provide some insight into the transport pathways associated with
477 changes in aerosol composition, questions regarding the aerosol precursor sources and
478 mechanisms contributing to the observed multi-day and seasonal variations in aerosol
479 composition are best addressed by regional chemical model studies. The data set also provides a
480 useful metric to evaluate global model predictions of aerosol composition.

481 **4. Summary and Conclusions**

482 In this study the long-term seasonal, diurnal, weekly, and monthly trends for NR-PM₁ mass
483 concentration and composition are summarized for the SGP site. High mass concentration
484 periods of NR-PM₁ occur predominantly in the spring and winter months, due to increased
485 emissions of BBOA and formation of ammonium nitrate, respectively. Back trajectory analyses
486 show that BBOA during the spring is mainly from local burning emissions. Cooler ambient
487 temperatures that favor gas-to-particle partitioning and long-range transport of NO_x and
488 ammonia from urban and agricultural areas, respectively, resulted in elevated concentrations of
489 ammonium nitrate during the winter. There are no significant seasonal trends in sulfate
490 concentrations and a mixture of local and regional sources are expected for sulfate. An
491 OACOMP VAP was developed allowing PMF to be performed on long term ACSM data using a
492 rolling window technique, which captures the dynamic variations of chemical composition and
493 concentration in the OA components over time. For the first time PMF analysis using the
494 OACOMP VAP was performed to determine distinct OA factors, which consist of BBOA and
495 two types of OOA, differing in degrees of oxidation. For most of the study organics are aged and
496 highly oxidized, with the exception to this occurring during biomass burning events. The rolling-
497 window PMF results uniquely capture the dynamic variations of atmospheric oxidation and age
498 for each of the PMF factors.

499 Long-term and high time resolution aerosol mass and composition measurements from this
500 study can be combined with meteorological, radiation, aerosol optical property, and size
501 distribution measurements from SGP to evaluate aerosol radiative forcing simulations. As this
502 dataset continues to expand, it will be useful for observing changes in aerosol composition and
503 concentration over multiple years. The aerosol composition data can also be coupled with other
504 ARM SGP measurements of meteorology, radiation, and aerosol optical and hygroscopic

505 properties to evaluate how well climate models represent the seasonal and multi-year variations
506 in aerosol radiative forcing at this site.

Table 1. Summary of the major NR-PM₁ species mass concentrations in units of $\mu\text{g m}^{-3}$ measured at ~ 30 min time resolution over entire study (Nov. 2010 – June 2012) with the average percent of total NR-PM₁ in parentheses.

	$\bar{x}\pm 1\sigma$	Median	Range	# of Points	DL ^b
Total	7.0±9.3	4.5	0.10 – 270	19148	-
Nitrate	1.5±3.0 (21%)	0.30	BD ^a - 42	19148	0.012
Sulfate	0.80±1.0 (12%)	0.40	BD - 9.6	19148	0.024
Ammonium	0.66±1.2 (9.4%)	0.17	BD - 12	19148	0.284
Chloride	0.020±0.040 (0.24%)	BD	BD – 2.0	19148	0.01
Organics	4.0±6.2 (57%)	2.8	0.10 – 201	19148	0.148
OOA-1	2.1±1.7 (30%)	1.7	BD – 45	19074	-
OOA-2	1.6±2.4 (22%)	0.90	BD – 62	19074	-
BBOA	0.41±3.1 (5.9%)	0	BD – 124	7077	-

636 ^a Below detection limit (DL). ^b30 minute detection limits in units of $\mu\text{g m}^{-3}$ reported by Ng et al.
637 (2011b). To determine DL for longer averaging times (t) multiply reported DL values by
638 $(t_{30}/t)^{1/2}$.

639
640

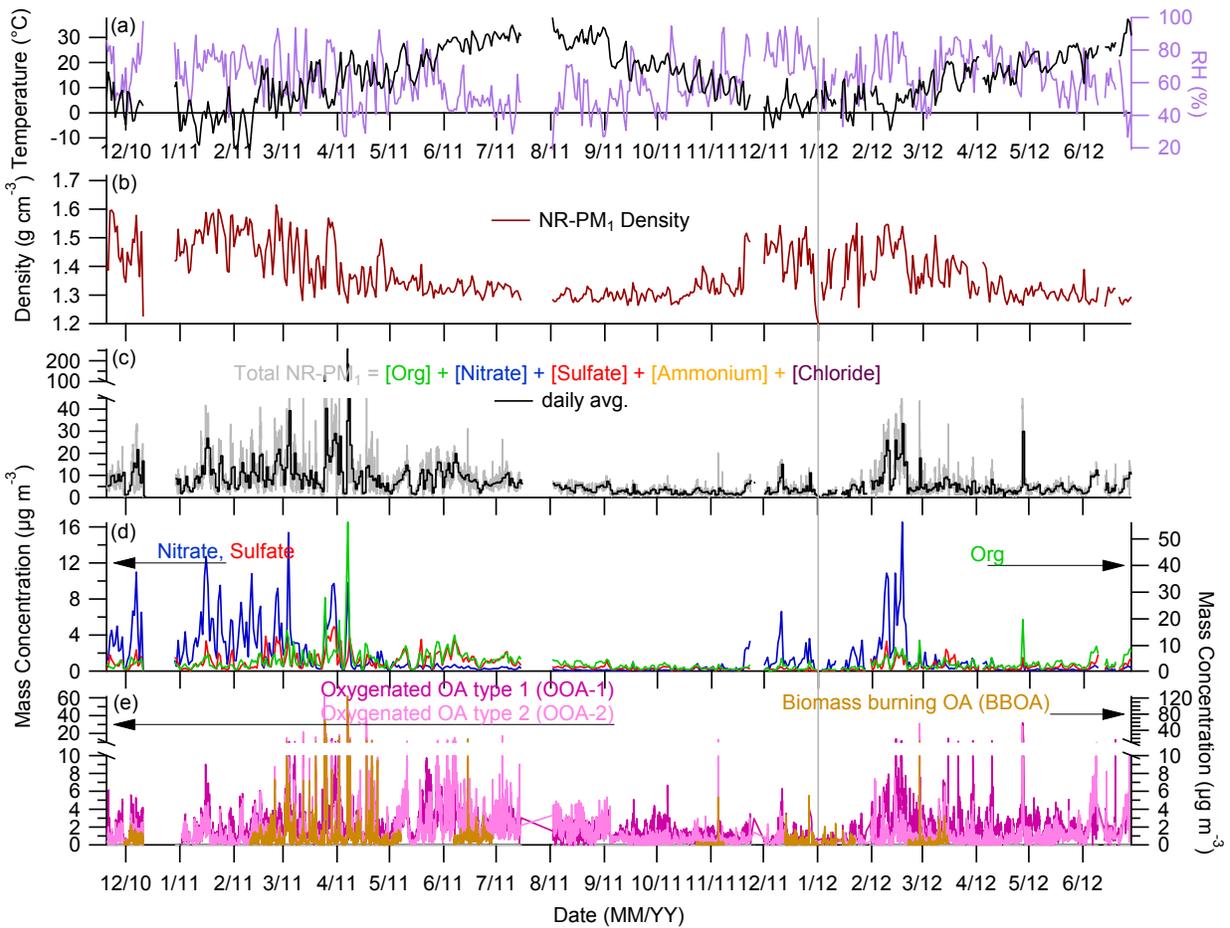

641 **Figure 1.** Plots (a-f) show back trajectories divided by season for 2010-2012 data with the
 642 SGP as the end point of each trajectory and are colored by frequency. Note that winter consists
 643 of December, January, and February; spring consists of March, April, and May; summer consists
 644 of June, July, and August; and fall consists of September, October, and November. Plots (g-h)
 645 show the emission rates for CO and isoprene, respectively. All maps have white dots that
 646 indicate SGP site location. Maps range from 30 to 50 N and 110 to 80 W.

647

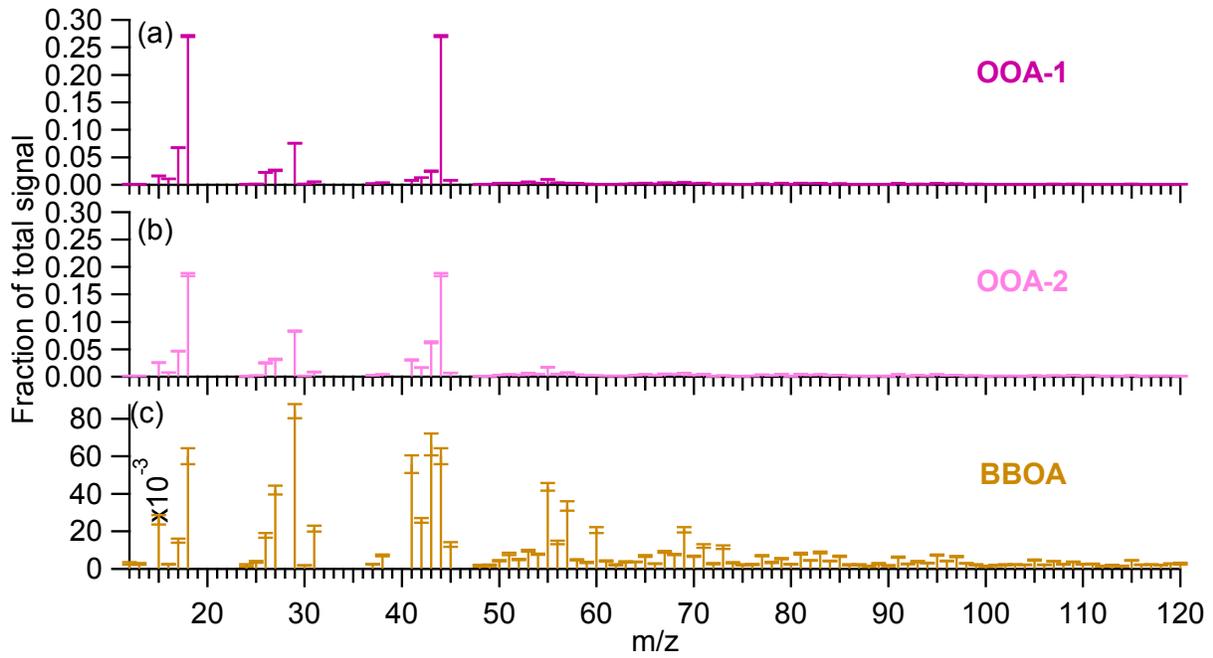

648

649 **Figure 2.** This figure shows the main results from the period 11/20/2010 – 06/28/2012.
 650 Shown here are: (a) the daily averaged temperature and relative humidity; (b) the calculated
 651 particle density using daily averaged time resolution; (c) the total mass concentration of NR-PM₁
 652 measured by the ACSM in 30 min. (gray) and daily (black) time resolution. (d) and (e) the daily
 653 averaged mass concentrations of organic and inorganic species. The gray vertical line that runs
 654 through all parts of Figure 2 divides 2011 and 2012 data. Note that y-axes are split in part c and
 655 e.
 656

657

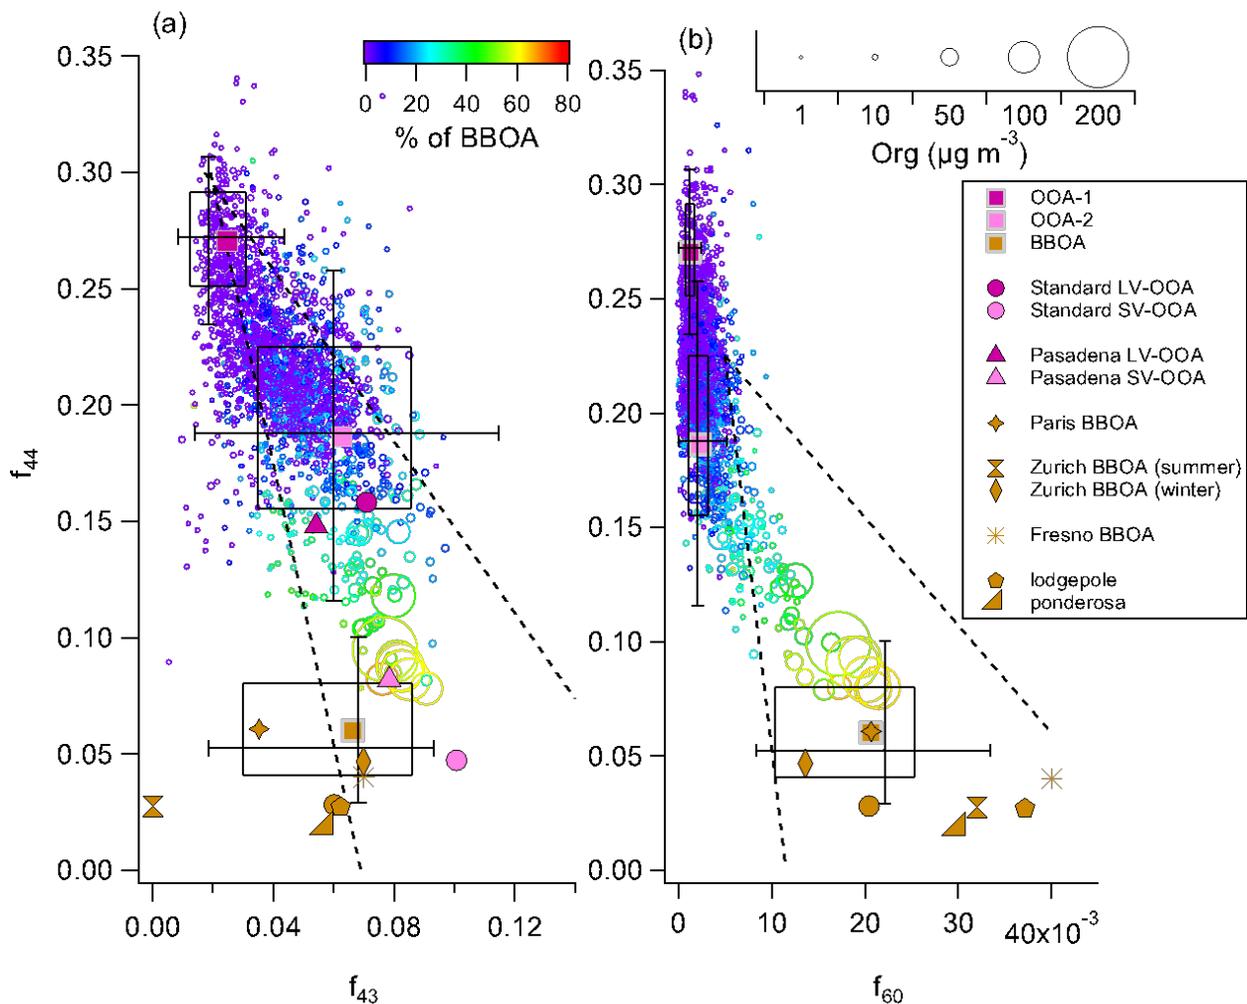

658 **Figure 3.** Average mass spectra of three components with standard error bars (a – c). The
659 percentage of the signal above m/z 120 is 3.6%, 3.4% and 8.0% for OOA-1, OOA-2 and BBOA,
660 respectively.

661

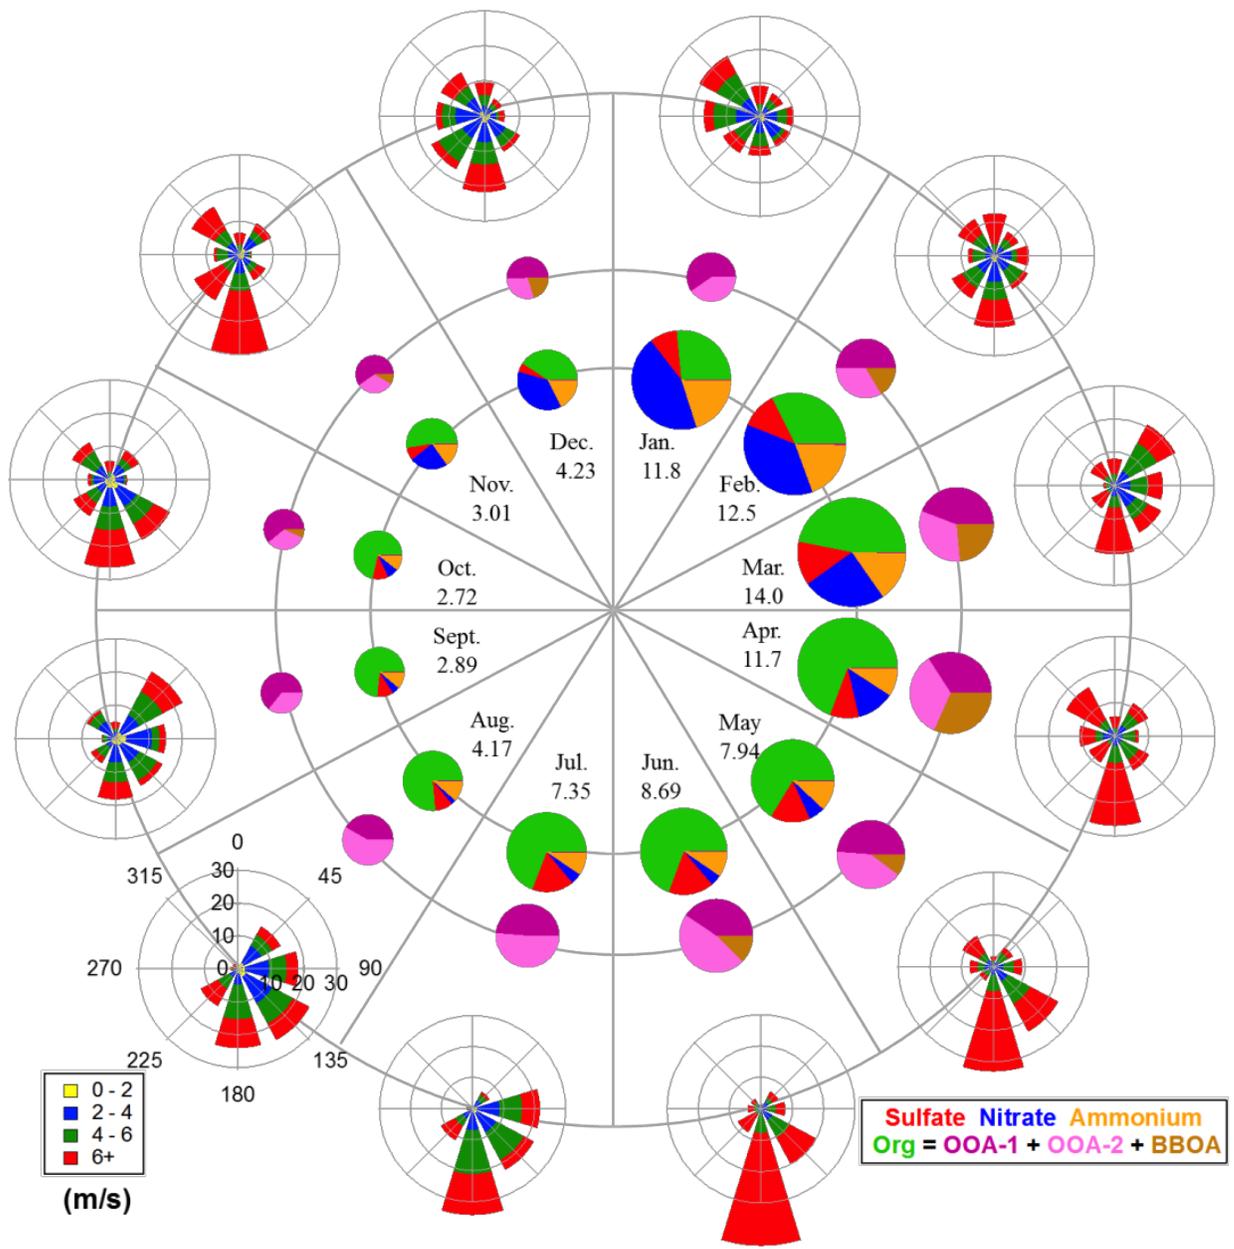

662

663 **Figure 4.** Triangle plot (a) shows the organic f_{43} versus f_{44} for the entire study (open circles)
 664 colored by percent of BBOA and sized by total organic mass concentration, using lines provided
 665 in referenced paper (Ng et al., 2010). Solid squares represent the mean f_{43} vs f_{44} values for the
 666 PMF factors OOA-1, OOA-2 and BBOA. The crosses are the median values and the left and
 667 right sides of the box (and bottom and top) are the 25th and 75th percentile, respectively, and the
 668 outer whiskers from left to right (and bottom to top) are the 10th and 90th percentile, respectively.
 669 Also included are f_{43} and f_{44} values from previous studies, including values for semi-volatile
 670 (SV-OOA) and low-volatility oxidized OA (LV-OOA) factors. A similarly formatted graph is
 671 shown in part (b) showing organic f_{60} versus f_{44} values. The triangle lines for plot (b) are adapted
 672 from Cubison et al. (2011).

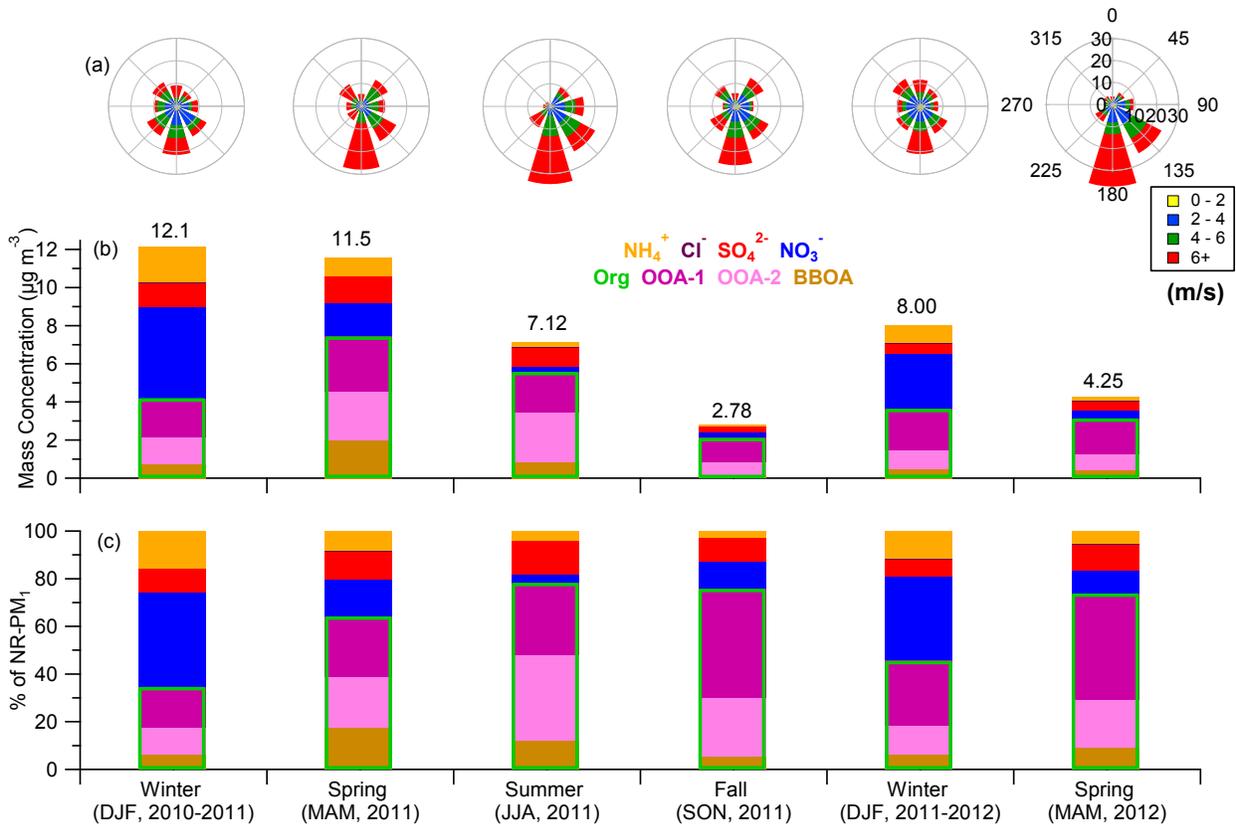

673

674 **Figure 5.** The monthly variations in average NR-PM₁ mass concentration, composition and
 675 wind data for one year (Jan. – Dec. 2011). The August wind rose is a reference for all wind roses
 676 shown, where the colors of the wind roses correspond to speeds listed in the left box. The middle
 677 pie charts show the average composition of organics and have areas that are scaled to total
 678 organic loading for that month. The inner pie charts show the average composition of NR-PM₁
 679 and have areas scaled by the average mass loading, written below each month in units of $\mu\text{g m}^{-3}$,
 680 during that month.

681
682

683 **Figure 6.** Seasonal characterization of wind and NR-PM₁ composition for 11/20/2010 –
 684 06/28/2012: (a) the averaged wind speed and wind direction for each season, (b) the seasonally
 685 averaged mass concentrations of NR-PM₁ species stacked together, and (c) the fractional
 686 contribution of each species to total NR-PM₁ mass concentration for each season. The key for the
 687 wind roses is shown on the far right wind rose on (a). The total averaged NR-PM₁ mass
 688 concentration is displayed above each bar in (b).

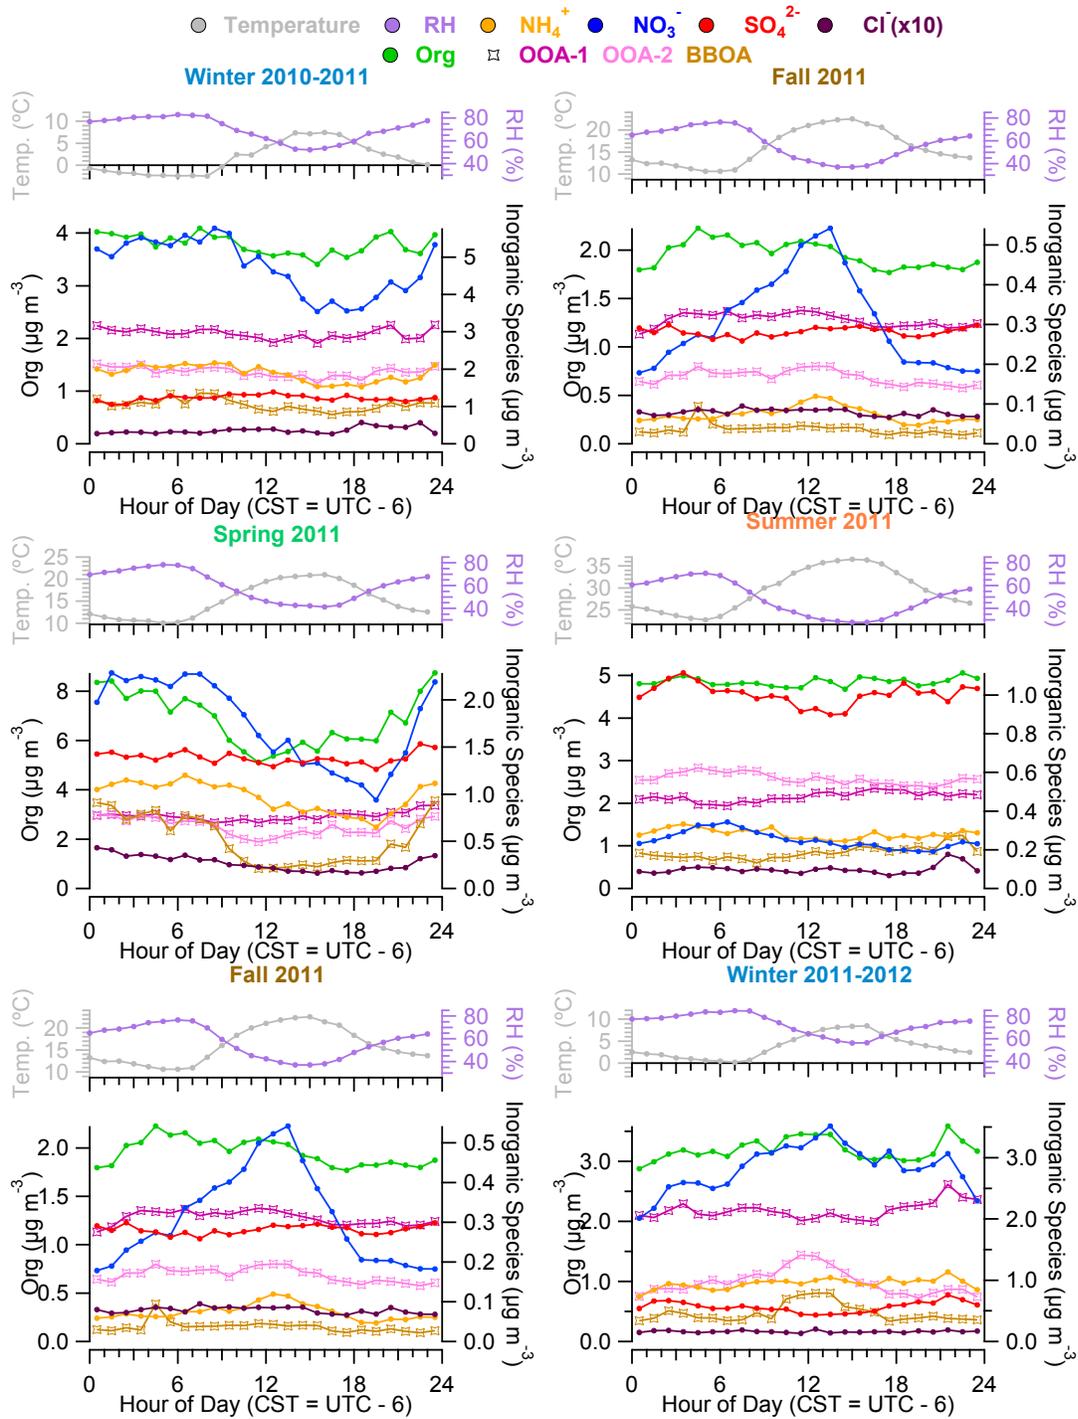

689

690

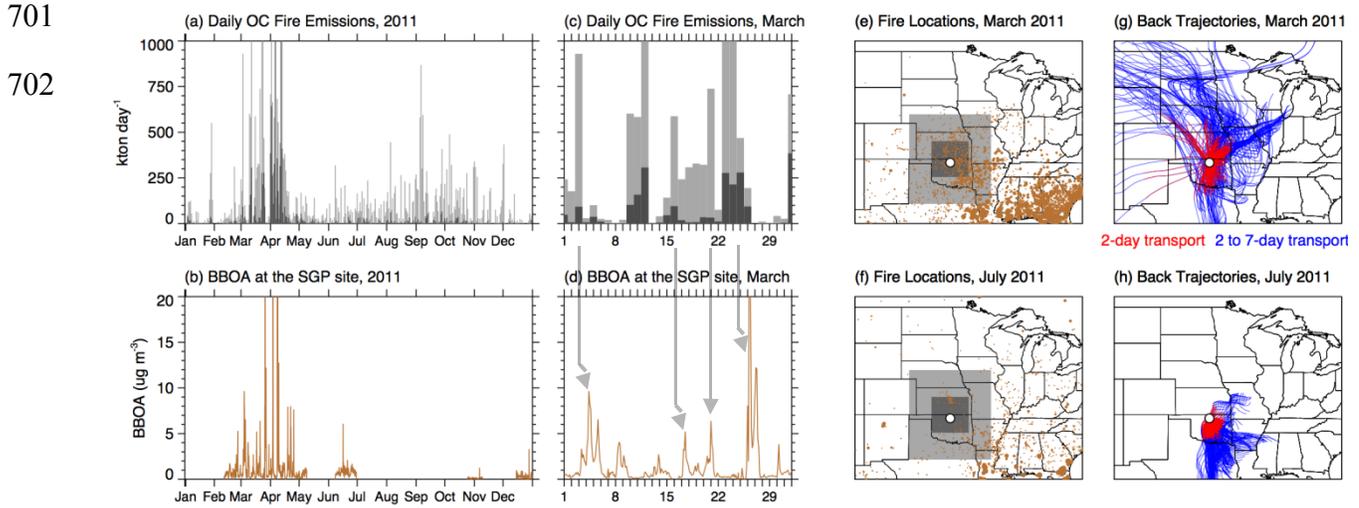

691

692 **Figure 7.** Diurnal variations of temperature, relative humidity (RH), and NR-PM₁ species
 693 mass concentrations at SGP for 11/20/2010 – 06/28/2012 summarized by season, with mean
 694 values shown here. Refer to Figure 1 for seasonal classification.

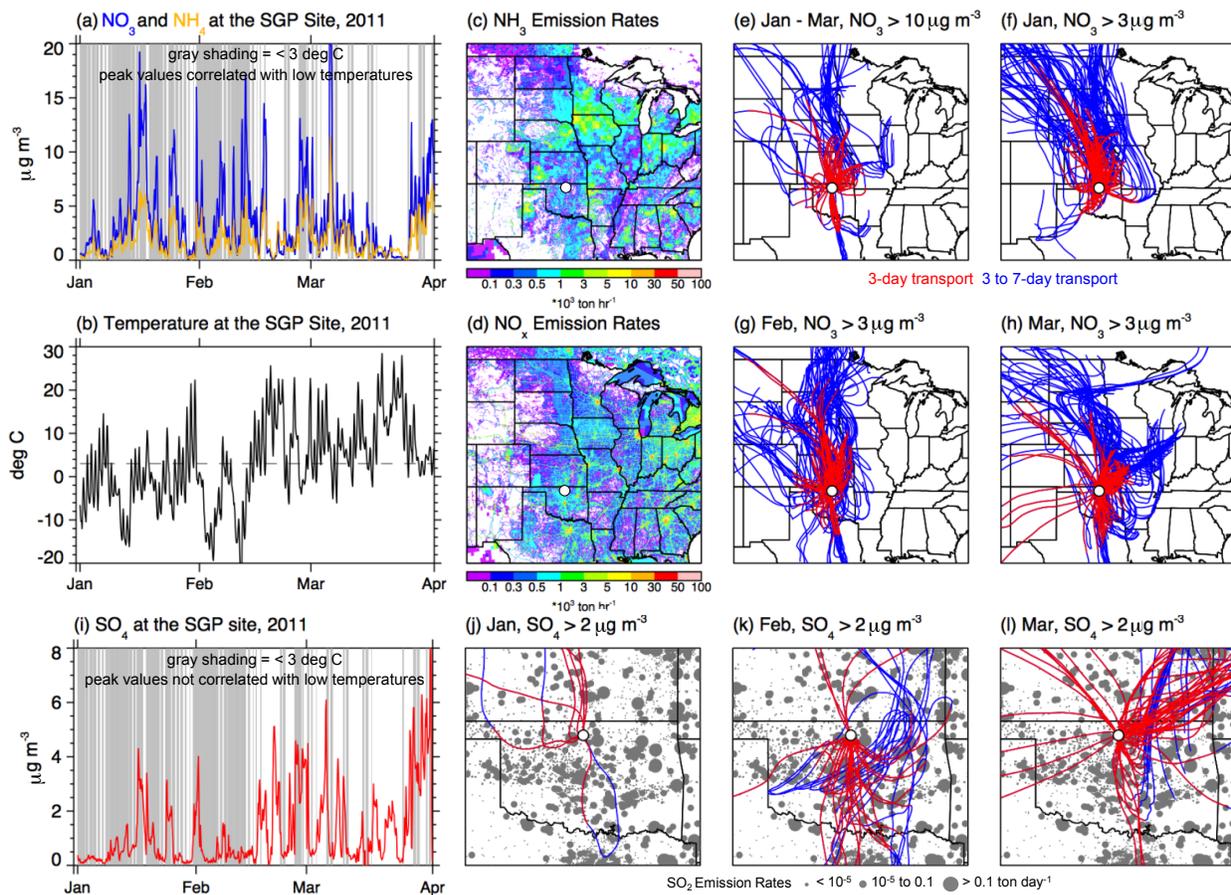

695

696 **Figure 8.** Daily fire emissions of organic carbon for 2011 (a) and March (c) at locations
 697 around SGP. The traces are colored according to the boxes highlighted in (e) and (f). Parts (b)
 698 and (d) show the daily observation of BBOA concentration at the SGP site for 2011 and
 699 specifically for March 2011, respectively. For months with BBOA emissions (March and July
 700 2011) fire locations (e, f) and back trajectories (g, h) are displayed, respectively.

703 **Figure 9.** Mass concentration time series for nitrate and ammonium for periods with high
 704 mass concentrations are shown in (a). Gray shading represents periods when temperatures at
 705 SGP site are below 3°C (dotted line in b). Emission maps for precursor gases including ammonia
 706 (c) and NO_x (d) are colored by emission rates. Back trajectories for nitrate including 3-day (red)
 707 and 3 to 7-day (blue) transport times to SGP site are shown in (e-h). Similarly formatted time
 708 series for sulfate shown in (i) and back trajectories shown in (j-l). Gray dots in (j-l) represent
 709 point sources of sulfur dioxide.
