17 ABSTRACT

18

19 We report on the first ever use of non-destructive micrometer-scale synchrotron-computed
20 microtomography (CMT) for biochar material characterization as a function of pyrolysis
21 temperature. This innovative approach demonstrated an increase in micron-sized macropore
22 fraction of the Cotton Hull (CH) sample, resulting in up to 29% sample porosity. We have also
23 found that initial porosity development occurred at low temperatures (below 350°C) of pyrolysis,
24 consistent with chemical composition of CH. This innovative technique can be highly
25 complementary to traditional BET measurements, considering that Barrett-Joyner-Halenda
26 (BJH) analysis of pore size distribution cannot detect these macropores. Such information can be
27 of substantial relevance to environmental applications, given that water retention by biochars
28 added to soils is controlled by macropore characteristic among the other factors. Complementing
29 our data with SEM, EDX and XRF characterization techniques allowed us to develop a better
30 understanding of evolution of biochar properties during its production, such presence of metals
31 and initial morphological features of biochar before pyrolysis. These results have significant
32 implications for using biochar as a soil additive and for clarifying the mechanisms of biofuel
33 production by pyrolysis.

40 INTRODUCTION

41

42 This work is focused on new applications of non-destructive micrometer-scale synchrotron
43 computed microtomography (CMT) to observe pyrolysis of biomass, which is of substantial
44 relevance for energy and environmental applications. Biochar is produced by high temperature
45 treatment of biomass (300-500°C and above) in the absence of oxygen (pyrolysis). This
46 treatment results in a product (biochar) comprising primarily of organic carbon^{1,2}. This approach
47 allows agricultural industry to reduce its carbon footprint by storing pyrolyzed biomass in soil
48 with an estimated residence time ranging from 5-29 years to 1,300-2,600 years depending on
49 references cited^{3,4}. In addition, there are other benefits from the study of biochar properties. For
50 example, biochar is a by-product of biofuel production and mechanistic knowledge of biochar
51 formation can be invaluable in understanding the chemical pathways of biofuel production.

52

53 Among many physicochemical parameters of biochar, it is important to single out porosity as it
54 has a significant influence on water retention and adsorption properties. Although some porosity
55 is naturally present in biomass, most of it comes from removal of various organic constituents of
56 biomass that have variable temperature stability^{5,6}. Together with specific surface area, porosity
57 plays a major role in predicting water retention by biochar and can also aid in understanding of
58 water adsorption and desorption behavior⁷. Computed tomography (CT) offers a very unique
59 insight into such behavior. There are already a number of studies on using CT to image
60 geological and soil samples⁸⁻¹⁰. For example, a recent study of soils where biochar was added
61 resulted in pore size reduction of the soil sample, contributing to a better water retention^{11,12}.
62 Although no published work followed biochar pyrolysis trends with CT, there was a recent work

63 on pyrolysis of oil shale. Using CT the authors were able to image three-dimensional pore
64 network structure developed due to pyrolysis, which was coupled with lattice Boltzmann
65 simulation of flow through the pore network⁸. In this paper we present the first ever application
66 of 3D X-ray synchrotron based computed microtomography (CMT) to elucidate the pore
67 structure development of biochars. Given the spatial resolution of CMT this paper primarily
68 focuses on macropores in the micrometer range, although smaller mesopores (<50nm) and
69 nanopores (<2nm) are also expected during the pyrolysis⁵. This is an important pore size range,
70 especially for water retention and release^{11, 12}

71

72 MATERIALS AND METHODS

73 Cottonseed hulls (hereby denoted CH) were pyrolyzed at 25, 350, 500, 650 and 800 °C for 4 h
74 under 1600 mL min⁻¹ N₂ flow rate using a laboratory scale box furnace (22 L void volume) with
75 a retort (Lindberg, Type 51662HR, Watertown, WI). The resulting chars (CH25, CH350,
76 CH500, CH650 and CH800) were allowed to cool to room temperature overnight under N₂
77 atmosphere.

78

79 Samples were scanned using 3D X-ray Computed Micro Tomography (CMT) at the X2B beam
80 line at the National Synchrotron Light Source at Brookhaven National Laboratory. The apparatus
81 uses a 1340 x 1300 pixel CCD camera with a pixel size of 4μm to acquire radiographs of the
82 sample using a CsI area x-ray detector. A total of 1200 radiographs were acquired as the sample
83 was rotated through 180°. The results were converted into a tomographic volume and visualized
84 using open-source software. The results give a 3-dimensional view of the linear attenuation
85 coefficients for each voxel. The linear attenuation coefficient is defined by the mass attenuation

86 coefficient in cm^2/g times the material density. The x-ray energy used for the work was 12.9
87 keV. Metal contents of the materials were also investigated using micro x-ray fluorescence
88 (XRF) techniques at NSLS beam line X27A. The beam size was 10 μm .

89
90 The Scanning Electron Microscopy (SEM) images, which also included elemental analysis, were
91 obtained using Field Emission Scanning Electron Microscope (SEM) LEO Gemini 1550
92 equipped with Schottky Field Emission gun (20 KV) and a Robinson backscatter detector. The
93 samples were coated with gold for 20 seconds using the low vacuum sputter coater to prevent
94 charging.

95

96 RESULTS AND DISCUSSION

97

98 A 3D CMT reconstruction of unpyrolyzed cottonseed hull (CH) is shown in Figure 1-A.
99 This reconstruction is representative of a CH fragment used in our experiments. In addition to
100 scale bar, the image also has X-ray attenuation color scale, which can be used to study porosity
101 development during the pyrolysis as illustrated below. For reference purposes we also included
102 the SEM image of CH. An important advantage of 3D CMT as compared to SEM is a CMT
103 capability to image multiple cross sections of the sample in a non-destructive way. A cross
104 section of the unpyrolyzed sample is presented in Figure 2-A. It indicates that the untreated
105 sample does not have significant porosity, although given that the resolution of the technique is
106 on μm scale, smaller pores would not be revealed by the CMT measurements. In contrast to the
107 untreated sample, a dramatic increase in porosity due to pyrolysis is revealed in the cotton hull
108 cross section taken after pyrolysis at 650°C displayed in Figure 2-B. It is also important to note

109 that the most significant development of porosity occurs at lower temperatures of pyrolysis, as
110 obvious from comparison of 350°C pyrolyzed samples (Figure 2-C) and 500°C pyrolyzed
111 sample (Figure 2-D). As soon as the outer layer is removed at temperatures of around 800°C, the
112 samples tend to disintegrate into small pieces (Figure 2-F). These dramatic changes in the
113 structures are caused by the destruction and vaporization of specific components of the cotton
114 hull that have different temperature stability. In general the components of biomass include such
115 constituents as cellulose, hemicellulose and lignin¹³. Hemicellulose can decompose at
116 temperatures around 150-350°C, while cellulose will be degraded at 280-350°C^{14,15}. The most
117 stable component, lignin, will undergo the chain fragmentation at around 300-480°C¹⁶. In case of
118 CH, it primarily consists of cellulose with a minor presence of lignin compounds^{17,18}, the most
119 significant development of porosity occurs at temperatures below 400°C as indeed observed in
120 Figure 2. From another perspective, CH can be described in terms of labile and more recalcitrant
121 to microbial degradation carbon fractions¹⁹. In our previous work⁶ we have determined that
122 pyrolysis of CH between 200-800°C resulted in increased fixed carbon from 22.7 to 77.1 wt.%
123 which was accompanied with a decrease in labile carbon. A more detailed information on
124 increase in fixed carbon and ash content, and decrease in volatile matter content are shown in
125 supplementary information (Tables 1 & 2) This is also consistent with our previous work on in-
126 situ characterization of pyrolysis with DRIFTS, where the greatest change in surface
127 functionalities was observed in 200-500°C pyrolysis temperature range⁶. It is important to
128 mention that development of stable graphitic (recalcitrant) structure of carbon during the
129 pyrolysis is intimately linked to the chemical composition of biomass, although there is a
130 scientific debate about the role of mineral content in forming porous structures and the sensitivity
131 of the biochar structure development to the original composition of biomass²⁰.

132

133 Figure 3 shows the linear attenuation coefficients for CH pyrolyzed at different
134 temperatures. The x-ray linear attenuation coefficient, μ , is defined by the equation $I/I_0 = e^{-\mu x}$,
135 where x is distance traversed by the x-ray. It is dependent on the elemental composition of the
136 material and measures the variability of the CH composition on a micrometer size scale. This
137 capability gives new insights into the values found from conventional macroscopic analytical
138 techniques. The plot shows a well-defined peak for the solid material at a value of 2.45cm^{-1} for
139 the CH prior to pyrolysis. We estimated the X-ray mass attenuation coefficient expected for CH
140 material taken as C(45.8%), H(5.5%), O(40.3%), Mg(2.09%), P(0.32%), K(4.26%), Na(0.02%),
141 and Ca(1.75%) using tables from the National Institute of Standards and Technology²¹. In
142 addition, measured concentrations for the heavy elements are given in the supplemental material.
143 The density of cotton hull was taken as 0.19g/cm^3 . As mentioned above, the calculated linear
144 attenuation coefficient (cm^{-1}) is just the product of the two factors: the x-ray mass attenuation
145 coefficient and the density. The calculated value is about 30% higher than the measured value.
146 The agreement is excellent considering the uncertainties in the factors entering into the
147 calculated result. The attenuation from the metals is roughly equal to the attenuation from the
148 organic materials and is found throughout the measured mass of the CH.

149

150 The effect of pyrolysis is to broaden the measured attenuation distribution to both higher
151 and lower values. The increase in the higher values comes from an increase in the concentrations
152 of the heavy elements (See Supplemental material) combined with any increase in density of the
153 materials caused by the pyrolysis. The increase in lower values can mainly be ascribed to loss of
154 organic materials and the associated increase in porosity and the corresponding decrease in bulk

155 density. Of course, changes in the metal distributions are also possible. Extension of the XRF
156 mapping to measurements on these sections of the CH pyrolyzed material is necessary to clarify
157 this question.

158
159 Detailed estimates of the microscale porosity of the materials were made by fitting the
160 peaks attributed to porous and solid regions (Figure 4). The results indicate a dramatic increase
161 in the porosity as a result of increase in pyrolysis temperature. Whereas the section at the
162 beginning of pyrolysis showed no porosity, the sample pyrolyzed at 800°C showed 29%
163 porosity. Importantly, there was a dramatic increase in porosity at the low temperatures
164 following the sequence, whereas at higher temperature the porosity remained relatively stable:
165 (1) unpyrolyzed sample having no porosity; (b) sample pyrolyzed at 350 °C sample having the
166 porosity of 0.27; (c) sample pyrolyzed at 500 °C having porosity of 0.23; (d) sample pyrolyzed at
167 800 °C having porosity of 0.29. Our data demonstrate that at the beginning of pyrolysis the heat
168 treatment results in the creation of macropore content in the biochar. This is an important result
169 for two reasons. First, conventional BET measurements and pore size calculations using, for
170 example, BJH method do not detect the macropores. It is instructive to mention that for the
171 porosity calculated from pycnometry data, the published data indicate that overall porosity (e.g.
172 for hazelnut shell and douglas fir) remains stable above 370 °C heating temperature²². This was
173 attributed to stable fraction of macropores, which we also observed. The only porosity increasing
174 above that temperature is related to nanopores formation, which contribute only a small fraction
175 to the overall porosity. Second, since water retention by biochars in soils is controlled by the
176 macropores (among other parameters such as hydrophilicity of the surface), application of
177 tomography will be a powerful analytical method in the future, especially in the size range

178 (micron size macropores) which other techniques do not cover. Given a capability of 3D
179 reconstruction of pore interconnectivity, comprehensive modeling efforts can be capable of
180 providing unprecedented level of details for understanding water transport and retention.

181
182 The metal content of the CH was explored using both synchrotron XRF and SEM-EDX
183 techniques. The synchrotron work was done at the NSLS X26A beam line. The apparatus is not
184 instrumented for detection of the very light elements such as C, N, and O. For this reason,
185 measurements were also made with the SEM-EDX equipment that was optimized for light
186 element detection. Results from the synchrotron measurement (Supplementary Info Figure S1)
187 indicate a significant presence of metals, including Mn, Fe, Ca, K, Ni, Cu and Zn. It is important
188 to mention that XRF mapping of individual elements in a grain-scale biochar sample
189 (Supplementary Info Figure S2) indicated that there is a significant heterogeneity in the spatial
190 distribution of these metals. This suggests the need for further work to map the distributions on
191 metals within the samples, especially for the sections where there is the most preserved solid
192 structure. Given the significant number of possible mineral phases in biochar²³, further work
193 might also be need to identify some of those phases given the importance of mineral content in
194 pore forming structures. The special heterogeneity in chemical composition might explain some
195 discrepancy in type of metals identified by XRF (Supplementary Info Figure S1) and SEM
196 (Supplementary Info Figure S3), which is also complemented by analysis of total elemental
197 content²⁴ determined by microwave digestion and EDTA extraction (Supplementary Info Table
198 S1).

199

200 The SEM results (Figure 4A-D) of the unpyrolyzed sample showed a presence of surface
201 associated pores, which were not obvious in the CMT results (Figure 2-A). The reason for
202 detecting these pores is based on higher resolution of the SEM technique, which is measured in
203 nanometers rather than micrometers for CMT. Moreover, the SEM images surface structures
204 whereas CMT shows cross section of the samples. Although SEM technique has been well
205 established for characterizing biochars²⁵, it was noted that observing trends in porosity
206 development strongly depends on biochar preparation conditions⁵. Indeed the images of
207 pyrolyzed samples (Figure 4E-H) did not reveal a consistent trend in porosity development,
208 possibly due to the above mentioned fact that only the surface of the sample was imaged as
209 compared to sample cross-sections (Figure 2) obtained by CMT. This lack of observed trends is
210 also consistent with published work on pyrolysis of sawdust where the samples prepared without
211 a prolonged temperature holding time did not demonstrate a clear trend in porosity observed in
212 SEM images⁵. The same work also suggests that porosity can be adjusted by tuning the biochar
213 preparation conditions, such as introduction of fast pyrolysis^{5, 26}. Finally, the EDX analysis of
214 elemental composition (Supplementary Info Figure S3) appeared to be not as sensitive as that of
215 XRF analysis by synchrotron based technique, as obvious from the fact that fewer metals were
216 detected in the sample (e.g. K, Mg and Ca). As discussed earlier, this is consistent with SEM
217 being more sensitive to alkali and alkaline earth metals as compared to XRF. In addition, this
218 discrepancy can be also attributed to a very heterogeneous nature of the samples, as analysis
219 depth and analysis spots were different for SEM and XRF techniques.

220

221 CONCLUSIONS

222

223 The results of CMT, SEM, EDX and XRF analysis of biochar samples presented in this
224 publication illustrate the very important advantage of adding CMT-based image analysis to the
225 usual analytical techniques since it gives a refined understanding of porosity development in
226 biochar. This is critical in obtaining refined understanding of both fundamental and applied
227 aspects of biomass pyrolysis. We believe that this first ever demonstration of using synchrotron-
228 based CMT techniques for biochar imaging has significant importance for both environmental
229 and biofuels research areas.
