2425 **Abstract:** We present a framework for calculating the total scattering of both non-
26 absorbing and absorbing aerosol at ambient conditions from aircraft data. Our framework
27 is developed emphasizing the explicit use of chemical composition data for estimating the
28 complex refractive index (RI) of particles, and thus obtaining improved ambient size
29 spectra derived from Optical Particle Counter (OPC) measurements. The feasibility of our
30 framework for improved calculations of total scattering is demonstrated using three types
31 of data collected by the U.S. Department of Energy's (DOE) aircraft during the Two-
32 Column Aerosol Project (TCAP). Namely, these data types are: (1) size distributions
33 measured by a suite of OPC's, (2) chemical composition data measured by an Aerosol
34 Mass Spectrometer and a Single Particle Soot Photometer, and (3) the dry total scattering
35 coefficient measured by an integrating nephelometer and scattering enhancement factor
36 measured with a humidification system. We demonstrate that good agreement (~10%)
37 between the observed and calculated scattering can be obtained under ambient conditions (

38 $RH < 80\%$) by applying chemical composition data for the RI-based correction of the
39 OPC-derived size spectra. We also demonstrate that ignoring the RI-based correction or
40 using non-representative RI values can cause a substantial underestimation (~40%) or
41 overestimation (~35%) of the calculated scattering, respectively.

48 1. Introduction

49 Although the importance of atmospheric aerosol in modifying the Earth's radiation budget has been
50 recognized by many studies [1,2], the extent to which aerosol shapes the regional and global climate is
51 still ambiguous [3,4]. The magnitude and sign of the aerosol-induced changes of the radiation budget
52 at the regional and global scales are highly uncertain, since these changes are influenced substantially
53 by strong temporal and spatial variations of aerosol loading, chemical composition and mixing state [5-
54 7]. Since the advent of observational techniques for monitoring these variations from surface, air and
55 space, the diversity of sensors with improved precision and accuracy has increased and corresponding
56 innovative methods have been developed [8-11]. Aircraft measurements are becoming increasingly
57 important for model validation studies because they can document aerosol variations in remote regions
58 where access to ground-based observations is difficult or unavailable, and offer observations with
59 higher temporal resolution than can typically be attained with satellites [12-14].

60 Comprehensive and integrated measurements of aerosol properties provide an important
61 observational basis for evaluations of climate model predictions and necessarily involve combining
62 data collected by several instruments with different designs and uncertainties. To determine whether
63 these data are consistent and reasonable, a special kind of quantitative comparison experiment is
64 commonly performed. Such an experiment, traditionally referred to as a closure study, compares the
65 measured values of a selected aerosol property with those calculated from independent measurements
66 [15-18]. For example, an optical closure experiment compares the measured values of an aerosol
67 optical property, such as total scattering coefficient, with those calculated from independently
68 measured size distributions and chemical composition under a variety of conditions [19-21]. Good
69 agreement between the measured and calculated aerosol properties (within error bars) indicates
70 consistency of the observational dataset, and bolsters its relevance for further use in global and
71 regional climate model evaluations.

72 Optical closure studies have become an essential part of testing integrated datasets where
73 simultaneous measurements of the optical, microphysical and chemical properties of aerosol at dry and
74 ambient conditions are available [21-23]. Compared to the ground-based instrumentation suites,
75 instrumentation on board aircraft platforms requires particular attention to its design and operation [24]
76 mainly due to payload restrictions (requiring instruments with smaller dimensions and less weight;

77 [25,26]) and abrupt changes in atmospheric and aerosol characteristics during the aircraft's rapid
78 (about 100 m/s) motion (requiring instruments with faster response time and data acquisition speeds;
79 [27]), which directly impact spatial resolution. While airborne instrumentation and associated data
80 synergy are continuing to evolve on many fronts, rigorous scrutiny of airborne integrated
81 measurements has not always been achieved. Moreover, demands to assess the consistency and
82 reasonableness of integrated airborne data sets have been growing, given the increasingly heavy
83 reliance of process-oriented model evaluations on aircraft measurements [28].

84 Optical Particle Counters (OPCs) are a common type of airborne instrument for deriving size
85 spectra [24,29,30]. The fundamental quantity measured by OPCs is the amount of light scattered by
86 individual particles over a large solid angle. The amount of scattered light depends on aerosol
87 characteristics such as size, shape and complex refractive index (RI), which is a function of the
88 particle's chemical composition. The measured scattered light is converted into particle size using an
89 appropriate scattering theory (e.g., Mie theory for spherical particles) and an assumed or estimated
90 refractive index. For example, several parameterizations have been developed for correcting OPC-
91 derived size distributions for weakly absorbing aerosol using Mie calculations and assuming that the
92 RI-based correction depends on the real part of the RI only [31,32]. It is important to note that the
93 assumptions employed for the refractive index may or may not be representative of the observed
94 ambient conditions.

95 Although Mie theory does allow for the RI-based corrections associated with both the real and
96 imaginary parts of the complex RI [33-35], airborne measurements of aerosol chemical composition
97 and absorbing components that are required for the RI estimation are demanding and not always
98 available. The mass loading of black carbon (BC) is an example of one of these absorbing components
99 with relatively sparse relevant measurements [4,36]. As a result, iterative schemes that use assumed
100 values of complex RI in combination with other assumptions are commonly applied to minimize
101 differences between the measured and calculated aerosol properties of interest, such as PM_{10} [35]. For
102 humid conditions, the particle size distributions exhibit a sensitivity to water uptake by particles [37],
103 and therefore the hygroscopic growth factor (HGF) and its dependence on particle chemical
104 composition must be considered in closure-related studies.

105 While closure studies using the microphysical, optical, chemical components, and ambient relative
106 humidity (RH) are a well-known framework that has been used intensively for decades [38-40], its
107 successful applications are mainly limited to the ground-based observations [21,41,42]. Given the
108 complexity of conducting airborne measurements and the growing demand to use these measurements
109 for process-oriented model validation and climate model assessments, there is a strong need to extend
110 this framework to comprehensive airborne datasets [22,43,44]. The primary purpose of our work is to
111 attempt to formally extend the framework for ground-based optical closure studies to airborne data sets
112 by answering the following three main questions:

- 113
- 114 (1) *What level of agreement can be achieved between the in-flight measured and calculated values*
115 *of total scattering coefficient at ambient RH ?*
 - 116 (2) *What is the effect of ignoring the influence of chemical composition data on this agreement?*
 - 117 (3) *How sensitive is this agreement to the assumed RI value, particularly if the assumed RI is non-*
118 *representative of the ambient aerosol?*

119 The first question is associated with the consistency of the airborne measurements of the particle size
120 distributions and optical properties when aerosol chemical composition data are available (a preferred
121 “complete” dataset). The second and third questions can be considered as “practical-oriented” because
122 they are focused mostly on practical situations when information on the chemical composition is not
123 available (an “incomplete” dataset) and several assumptions about aerosol composition are required.
124 Given that the dimension/weight of several instruments commonly deployed to measure the aerosol
125 chemical composition, such as the miniaturized version of the aircraft-compatible single particle mass
126 spectrometer (miniSPLAT; [45]) and the Aerodyne Aerosol Mass Spectrometer (AMS), is substantial,
127 they are deployed less frequently on mid-to-large size aerial platforms. Moreover, they cannot be
128 deployed on small aerial platforms, such as small or unmanned aircraft. To assess the extended
129 framework and evaluate the relevant assumptions through answering these three important questions,
130 we use integrated airborne data collected during the recent Two-Column Aerosol Project (TCAP;
131 <http://campaign.arm.gov/tcap/>) over the North Atlantic Ocean and US coastal region (Cape Cod,
132 Massachusetts, USA).

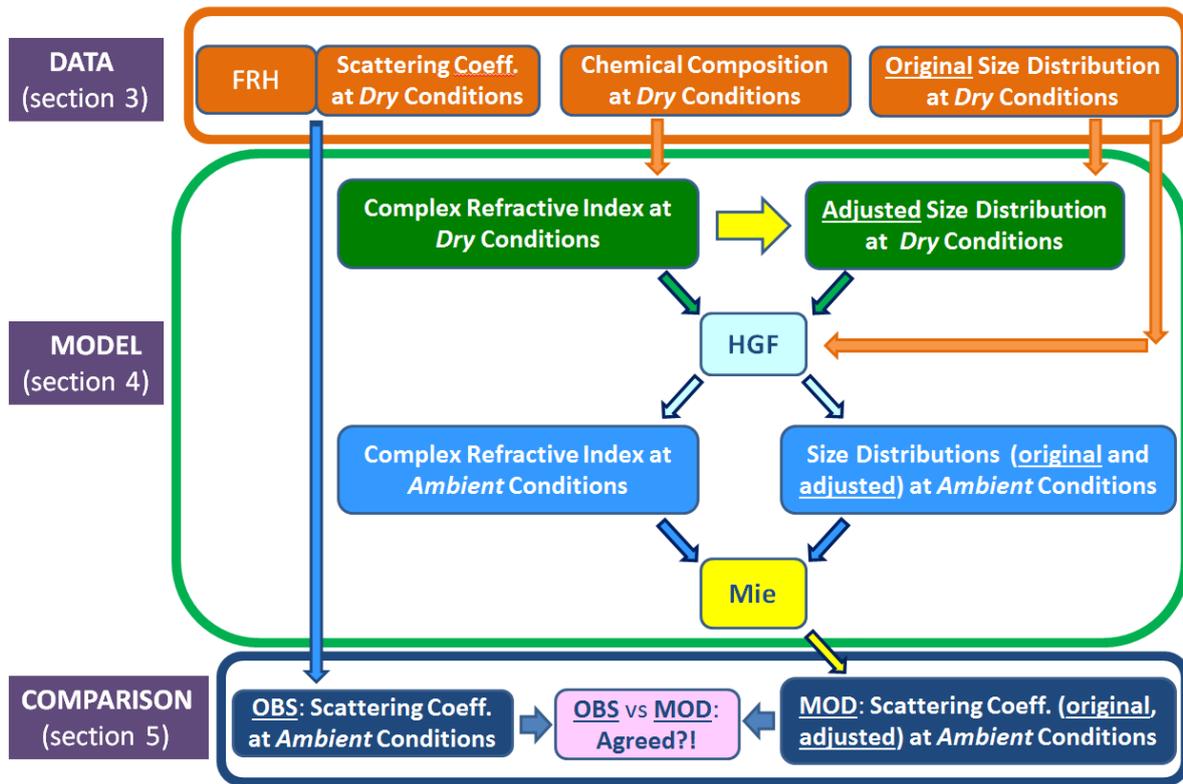

133 We outline in the next section our approach for extending the ground-based framework for
134 conducting optical closure experiments to airborne data. In section 3 we briefly describe the TCAP
135 data, which represent mainly non-absorbing aerosol and include measured size spectra, chemical
136 composition and total scattering [46]. The complementary model components of our approach and the
137 corresponding assumptions are discussed in section 4. These assumptions, such as the homogeneous
138 internal mixture, are reasonable and permit us to calculate the *HGF* and complex RI at ambient *RH*
139 when additional information is missing. In section 5, the calculated and measured total scattering
140 coefficients are compared for the wide range of atmospheric conditions observed during TCAP flights
141 conducted in July of 2012, including conditions with low and high ambient *RH*. The sensitivity of the
142 calculated scattering to the RI and related issues are further discussed in section 6. In particular, this
143 section emphasizes that the ability to make complementary measurements of chemical composition
144 holds promise for properly specifying the RI, and thus for improving the accuracy of total scattering
145 calculations. The last section presents a summary of key findings.

147 2. Approach

148 Figure 1 outlines the major components and main steps in conducting our optical closure
149 experiment by obtaining total scattering coefficients at ambient *RH* from airborne measurements and
150 Mie calculations.

151 **Figure 1.** Schematic diagram summarizing the framework for an optical closure
152 experiment using airborne data. The figure illustrates the link between the measured dry
153 and ambient scattering coefficients (**left-hand** part of diagram; top and bottom panels) and
154 the connection between the measured dry chemical composition/size spectra and the
155 calculated ambient scattering coefficient (**central** and **right-hand** parts of diagram).
156 Ambient size spectra (light blue, right) are obtained from the dry size distributions without
157 (orange) and with (green) the RI-based correction, respectively. The estimated ambient size

158 spectra (light blue, right) together with the ambient RI (light blue, left) are required as
 159 input for Mie calculations (yellow) of the corresponding total scattering coefficients (navy
 160 blue, right). See indicated text section for details of each component (Data, Model,
 161 Comparison).
 162

163
 164

165 Although our approach relies heavily on several important components and assumptions, such as
 166 homogeneous internal mixture and spherical geometry of particles, introduced earlier by previous
 167 studies [21,37,42,47], well-known challenges experienced in collection and interpretation of airborne
 168 data make evaluation of this unified approach mandatory. Our approach, as displayed in Figure 1,
 169 involves three major components: (1) integrated measurements of aerosol properties (Figure 1; top
 170 panel), (2) calculations of the ambient scattering coefficient using Mie theory and estimated
 171 hygroscopic growth factor (HGF) (Figure 1; middle panel), and (3) comparison of the scattering
 172 coefficients observed and calculated at ambient conditions (Figure 1; bottom panel). Note in Figure 1
 173 how chemical composition information becomes encoded into the improved size spectra, making
 174 calculations of scattering more accurate. The left-hand part of diagram (Figure 1; top and bottom
 175 panels) illustrates the process of obtaining the observed total scattering at ambient conditions. For the
 176 TCAP data set used in this work, this step involves analyzing the total scattering measured by an
 177 airborne nephelometer at low RH and the light scattering hygroscopic growth $f(RH)$ measured using
 178 a humidification system. The central part of diagram (Figure 1; top and middle panels) illustrates how
 179 the complex RI at dry conditions, derived from the chemical composition data, is used to adjust the
 180 particle size distributions. Note that the chemical composition data are also used to estimate the RH -
 181 dependent HGF . The latter is required for converting the dry complex RI and dry size spectra into
 182 their ambient counterparts. The right-hand part of diagram (Figure 1; top and middle panels)

183 demonstrates how the ambient size spectra are obtained from the original (without RI-based
184 correction) and adjusted (with RI-based correction) OPC-derived size distributions. The ambient
185 complex RI and size distributions (both original and adjusted) are used as input for the Mie
186 calculations. The output is the corresponding model total scattering coefficients calculated at ambient
187 conditions. As we shall see, differences between model coefficients calculated using the original and
188 the adjusted size distributions illustrate the importance of the RI-based correction for the total
189 scattering calculation.

190 3. Data

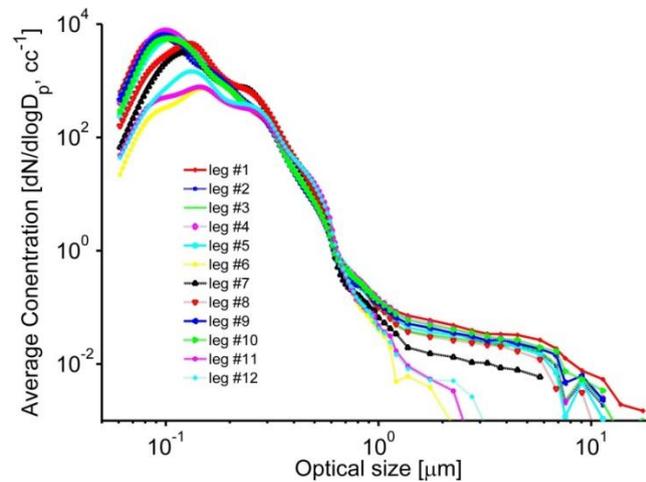

191 This section is meant to survey the observational components of our framework (Figure 1; top
192 panel) by reviewing the TCAP airborne data used in this investigation. The TCAP field campaign was
193 designed to provide a comprehensive data set that can be used to investigate important climate science
194 questions, including those related to aerosols. Conducted from June 2012 through June 2013, TCAP
195 involved summer and winter periods of intensive aircraft observations that included the U.S.
196 Department of Energy (DOE) Gulfstream-159 (G-1) aircraft. The G-1 typically sampled at multiple
197 altitudes within two atmospheric columns, one located over Cape Cod, MA and a second over the
198 Atlantic Ocean several hundred kilometers from the coast. Details of TCAP are given in *Berg et al.*
199 [46]. To illustrate performance of our unified approach (Figure 1), we focus on the TCAP summertime
200 data.

201 An in-situ instrumentation suite on board the DOE G-1 aircraft [24] together with airborne remote
202 sensing sensors, such as the Spectrometer for Sky-Scanning, Sun-Tracking Atmospheric Research
203 (4STAR; [26]) and the High Spectral Resolution Lidar (HSRL-2; [8]), were deployed during TCAP.
204 Note that the HSRL-2 was operated aboard a NASA B-200 aircraft. Here we focus on the instruments
205 relevant to our study to improve calculations of the total scattering coefficient at ambient conditions.
206 These calculations are based on Mie theory and require the ambient aerosol size distribution and
207 complex RI. Aerosol size spectra, chemical composition and total scattering data were collected with
208 high temporal resolution (< 1 min) during the TCAP flights. We use these data to compute the
209 corresponding averaged characteristics for each flight leg (FL), which is defined as a straight level run
210 at different altitudes with variable duration of approximately 5-15 minutes. We employ these FL-
211 averaged aerosol characteristics in our investigation, consistent with earlier studies [29,30,47].

212 Particle size distributions were measured simultaneously by three airborne OPC instruments: an
213 Ultra Sensitivity Aerosol Spectrometer (UHSAS, size range 0.06-1 μ m), a Passive Cavity Aerosol
214 Spectrometer (PCASP; size range 0.13-3 μ m) and a Cloud and Aerosol Spectrometer (CAS; size range
215 0.6- >10 μ m). These three instruments were mounted within PMS canisters on the same pylon
216 underneath the right wing of the G-1 aircraft. The UHSAS and PCASP were operated with anti-ice
217 heaters enabled and therefore the measured aerosol distributions are assumed to be dry. However, the
218 CAS measured particle size distributions at ambient conditions. All three instruments were calibrated
219 using polystyrene latex sphere (PSL) beads. The measured size distributions from the aforementioned
220 probes are recovered from the raw counts (taking into account collection efficiencies and sampling
221 volumes), merged, and smoothed (Appendix A) using a kernel based on Twomey's algorithm

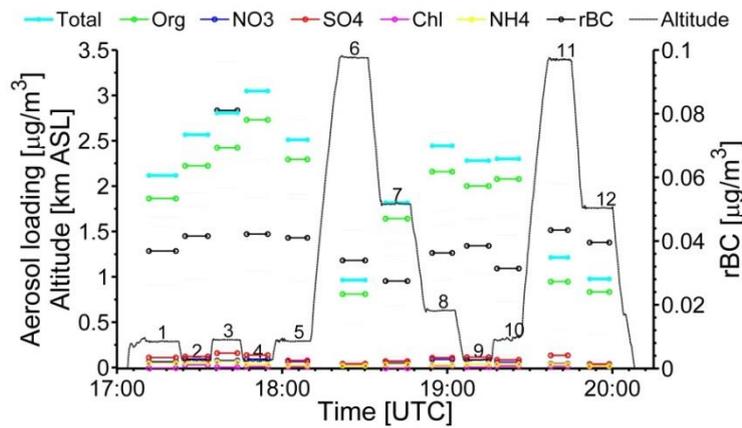

222 [43,48,49]. Figure 2 shows the resulting size distributions averaged over each FL on July 21, 2012.
 223 The altitude of each FL is shown in Figure 3.

224 **Figure 2.** Example of combined size distributions generated for each FL during a given
 225 day (July 21, 2012). Here and in the following plots, aerosol characteristics represent FL-
 226 averaged values. Elevation and time of each FL are shown in Figure 3.

227

228 **Figure 3.** Example of FL-dependent chemical compositions (colored lines) and BC (thick
 229 black lines) mass measured by the AMS and SP2, respectively (July 21, 2012). Also,
 230 altitude (thin black line) as a function of FL is included. FLs are labeled with numbers 1
 231 through 12 on top of the thin black altitude line.

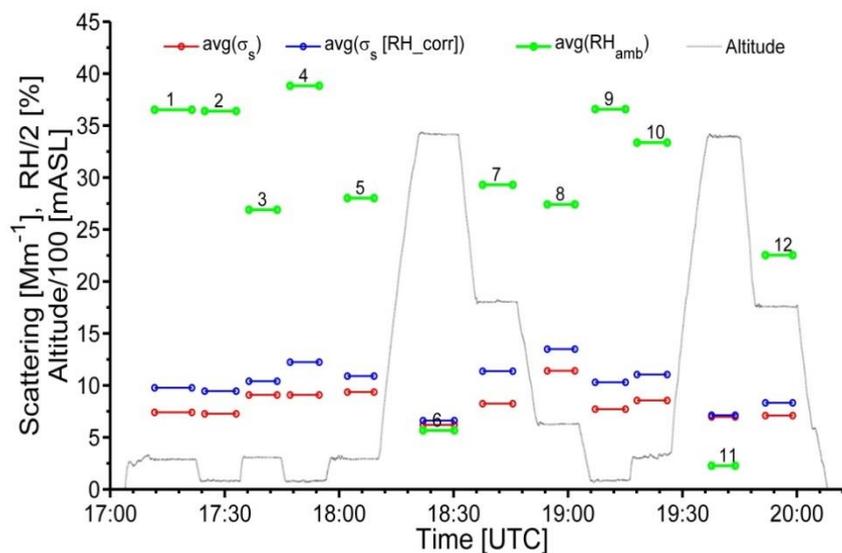

232

233 Particle size spectra measured by these three OPC instruments (UHSAS, PCASP, and CAS) cover
 234 different particle size ranges. However, these instruments employ a similar underlying operating
 235 principle for determining particle size, namely light scattering by individual particles. The conversion
 236 of the scattered light into particle size requires the RI, which depends on the chemical composition of
 237 particles, thus demanding an accurate RI estimation. During TCAP, information on the organic and
 238 inorganic species mass loading and black carbon (BC) mass in individual aerosol particles came from
 239 complementary Aerodyne AMS and Droplet Measurement Technology Single Particle Soot
 240 Photometer (SP2; 0.06-0.6μm range of mass-equivalent diameter; [50,51]) measurements, respectively
 241 (Figure 3). The AMS has a near unity transmission efficiency for particles with vacuum aerodynamic
 242 diameters between 0.06 and 0.6μm, which falls to 50% at 1 μm, and is negligible above 1.5 μm and

243 below $0.06\mu\text{m}$. The RH inside the SP2 does not exceed 10% and the AMS can differentiate particle-
 244 phase water from other species; therefore, the acquired chemical composition data represent dry
 245 conditions. Figure 3 illustrates that the aerosol chemical composition on July 21, 2012 was dominated
 246 by organic matter (OM); dominance of OM (generally greater than 70%) was observed for all TCAP
 247 flights [46].

248 **Figure 4.** The same as Figure 3, except for the dry scattering measured by nephelometer
 249 (red lines) and ambient scattering obtained with measured $f(RH)$ (blue lines) at $0.55\mu\text{m}$
 250 wavelength and ambient RH (green lines). FLs are labeled with numbers 1 through 12 on
 251 top of green lines.

252
 253 The total scattering coefficient at three wavelengths ($0.45, 0.55, 0.7\mu\text{m}$) was measured at dry
 254 ($RH < 20\%$) conditions using a TSI integrating nephelometer (Figure 4), while the light scattering
 255 hygroscopic growth, known as $f(RH)$, was measured using a humidification system at three defined
 256 RH s (near 45%, 65% and 90%) at a single wavelength ($0.525\mu\text{m}$) [52]. Similar to *Shinozuka et al.*
 257 [53], we adjust the $f(RH)$ obtained at the $0.525\mu\text{m}$ wavelength to the nephelometer wavelengths
 258 ($0.45, 0.55, 0.7\mu\text{m}$) by multiplying the obtained $f(RH)$ by 0.98, 1.01 and 1.04, respectively. The
 259 conventional truncation error correction [54] has been applied to the total scattering measured by the
 260 integrating nephelometer. We obtain the total scattering at ambient conditions (σ_{obs}) at three
 261 wavelengths ($0.45, 0.55, 0.7\mu\text{m}$) using both the adjusted $f(RH)$ and spectrally-dependent measured
 262 dry total scattering. It is to be noted that measurement uncertainties in the reported total scattering by
 263 the integrating nephelometer are quite small ($\sim 10\%$) for sub- μm , but can be considerable for super- μm
 264 particles ($\sim 50\%$) [54,55]. For a given FL, we assume that the combined uncertainty of σ_{obs} depends
 265 on its variability within FL (defined here as the standard deviation) and the measurement uncertainty
 266 [47]. In other words, the FL-dependent combined uncertainty in the ambient total scattering
 267 coefficient is comparable with the measurement uncertainty (10%) for a homogeneous FL and can
 268 exceed it substantially for an inhomogeneous FL where the standard deviation is large.

269 TCAP aircraft data were screened prior to use in our study. To ensure that only high quality data are
 270 used, two quality assurance screening criteria are applied. First, we check the data streams for

271 consistency between the size spectra, chemical composition and total scattering to prevent invalid data
272 entry. Second, we consider only periods in which all data streams are available. For example, PCASP-
273 measured size distributions were not available for several flights (e.g., July 14 and 15) and the
274 corresponding combined size distributions were generated from spectra measured by two instruments
275 (UHSAS and CAS) only. These combined distributions obtained without PCASP data are excluded
276 from our analysis. Similar to the size distributions, ambient scattering coefficients were not available
277 for some episodes as well. Given the large uncertainties of the obtained $f(RH)$ at very humid
278 conditions ($RH > 80\%$), the corresponding cases are also excluded from our analysis. Using the quality
279 assurance screening criteria reduces the size of the original dataset by about 30%. A total of 45 TCAP
280 FLs with the good quality data are included in our analysis. Further discussion of TCAP flight data
281 quality can be found in *Berg et al.* [46].
282

283 4. Model and Adjustments

284 This section outlines the model components of our framework for an airborne optical closure
285 experiment (Figure 1; middle panel) and describes the major assumptions required for estimating the
286 hygroscopic growth factor (section 4.1), ambient values of complex refractive index (section 4.2) and
287 correcting the OPC-derived size distributions (section 4.3). The RI-based corrections of the size
288 spectra together with estimates of HGF and complex RI form the basis for calculating the ambient
289 total scattering (section 4.4) with improved accuracy.
290

291 4.1. Hygroscopic growth factor

292 Water uptake by aerosol particles results in increased particle size and modifies the complex RI
293 [37]. To account for changes associated with water absorption, information on aerosol chemical
294 composition and hygroscopicity is needed. Typically, aerosol particles are a mixture of organic and
295 inorganic substances. We estimate the hygroscopic growth factor of the mixture (HGF_{mix}) from the
296 volume fractions of individual components (ε) and their growth factors as the volume-weighted
297 average [47]:

$$HGF_{mix} = \left(\sum_i \varepsilon_i HGF_i^3 \right)^{1/3} \quad (1)$$

298 We convert the mass fractions measured by the AMS and SP2 instruments (section 2) into the
299 required volume fractions using densities reported in literature and listed in Table 1. We emphasize
300 that the AMS and SP2 data are capturing a limited size range (sub-micron particles; section 2) only.
301 However, we use the AMS/SP2 data to infer the chemical composition of the entire size range (both
302 sub- and super-micron particles). The application of the AMS/SP2 data for the entire size range should
303 be appropriate for cases where the relative contribution of sub-micron particles to the scattering
304 coefficient is dominant. Given that the aircraft data collected during the TCAP data represent such a
305 favorable case with large contributions of sub-micron particles (Appendix B), application of the
306 AMS/SP2 data for the entire size range is appropriate.
307

Table 1. Assumed size-independent density, real and imaginary parts of complex refractive index (RI) at 0.55µm wavelength, and hygroscopic growth factor (*HGF*) values used in this study. Values are taken from [47,56,57].

	OM	SO ₄	NO ₃	Chl	NH ₄	BC	Water
Density (g/cm ³)	1.4	1.8	1.8	1.53	1.8	1.8	1.0
<i>RI</i> (real)	1.45	1.52	1.5	1.64	1.5	1.85	1.33
<i>RI</i> (imag)	0.0	0	0	0	0	0.71	0
<i>HGF</i> (RH=80%)	1.07	1.50	1.50	1.9	1.50	1.0	-

Although the growth factor can be quite sensitive to the particle size [21,58], we assume that particles with different sizes have the same HGF_{mix} . HGF_{mix} from Eq. 1 represents the hygroscopic growth factor at a specified relative humidity ($RH_{wet} = 80\%$). To obtain HGF_{mix} for a different humidity, we assume that HGF_{mix} follows the power law form [21,59]:

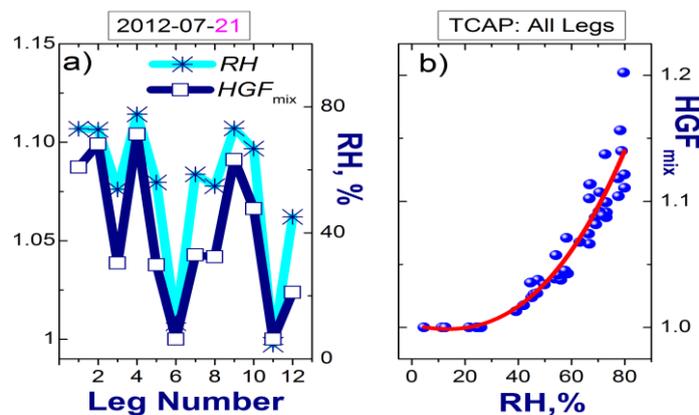

$$HGF_{mix}(RH) = \left(\frac{100 - RH_{dry}}{100 - RH} \right)^\gamma \tag{2}$$

where RH_{dry} is 30% . The dimensionless exponent γ is calculated as:

$$\gamma = \frac{\log(HGF_{mix}(RH_{wet}))}{\log\left[\frac{100 - RH_{dry}}{100 - RH_{wet}}\right]} \tag{3}$$

Recall that OM is the dominant component of aerosol sampled during the TCAP flights (Figure 2 and [46]). Given that the hygroscopic growth factor of the OM is relatively small compared to other chemical components (Table 1), the calculated RH -dependent HGF_{mix} does not exceed 1.3 and approaches 1 as RH decreases (Figure 5).

Figure 5. (a) Example of ambient RH and RH -dependent HGF_{mix} calculated for each FL during on July 21, 2012, and (b) scatterplot of RH -dependent HGF_{mix} (blue dots) for all TCAP FLs used in this study (section 3) with polynomial fit (red line).

4.2. Dry and wet refractive indices

We apply a volume weighting approach to calculate the real (n_{dry}) and imaginary (k_{dry}) parts of the complex RI (m_{dry}) of particles at dry conditions:

$$m_{dry} = \sum_i \varepsilon_i m_{dry,i} \tag{4}$$

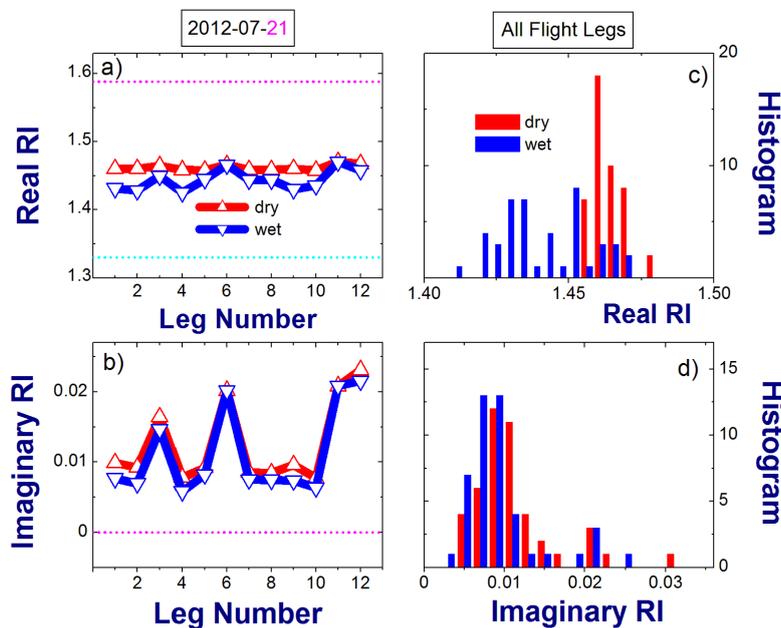

328 where $m_{dry,i}$ represents the real ($n_{dry,i}$) or imaginary ($k_{dry,i}$) part for each measured chemical
 329 component (Table 1). The underlying assumption of this popular approach is that the contribution of
 330 each chemical component to the light scattering and absorption is proportional to its volume fraction (ε_i). It should be emphasized that chemical composition, in general, depends on the particle size [58].
 331 The same is true for the real (n_{dry}) and imaginary (k_{dry}) parts of the complex RI [41]. Here we assume
 332 that particles with different sizes have the same chemical composition, and therefore the same RI.

333 The calculated dry RIs are applied to compute the corresponding ambient values [21,60]:

$$m_{wet} = \frac{m_{dry} + m_{water} (HGF_{mix}^3 - 1)}{HGF_{mix}^3} \tag{5}$$

335 where HGF_{mix} is the RH -dependent parameter defined in the previous section. As HGF_{mix} increases
 336 noticeably (near 1.1; Figure 5a), water becomes an influential component and the ambient RI decreases
 337 toward the water RI (Figure 6). In contrast, when HGF_{mix} is quite small (near 1; Figure 5a), the
 338 ambient RI increases toward the dry RI (Figure 6). Note that large values of the imaginary part of the
 339 RI (e.g., FL numbers 3, 6, 11 and 12) represent conditions where the relative contribution of BC to the
 340 total loading is substantial (>3%; Figure 3) and exceeds those for other FLs roughly by a factor of two.

341 **Figure 6.** (a,b) Example of RH -dependent dry and ambient values of the real and
 342 imaginary parts of the complex RI calculated for each FL during a given day (July 21,
 343 2012), and (c,d) the corresponding histograms obtained for all TCAP FLs. The real ($n_{OPC} = 1.588$) and imaginary ($k_{OPC} = 0$) parts of the complex RI used for OPC calibration
 344 are shown in Figure 6a (magenta) and Figure 6b(magenta), respectively. The real RI of
 345 water ($n_{water} = 1.33$) is also shown (Figure 6a,cyan). The imaginary RI of water ($k_{water} = 0$)
 346 is equal to the imaginary RI used for OPC calibration ($k_{OPC} = 0$).
 347

4.3. Size Distribution

There is a substantial difference between the RI used for OPC calibration ($n_{OPC} = 1.588; k_{OPC} = 0$) and the FL-dependent dry RI calculated from chemical composition data (Figure 6). To take into account this difference, we apply the RI-based correction to adjust the OPC-derived size distributions (see Appendix C for further discussion). It should be emphasized that the PSL-based OPC calibration applies a RI that very likely overestimates those for the typical sub-micron aerosol. Since a higher RI produces a larger scattering signal, a particle with smaller size and higher RI scatters the same as a particle with larger size and smaller RI. As a result, all of the adjustments of the OPC calibration to the actual RI will increase the size of measured particles, and consequently will increase the total scattering for almost any reasonable size distribution. Moreover, adding an absorbing component further increases the size of the measured particles – after adjustment – due to the reduction of the particle’s scattering and consequent decrease of its optical size. We will illustrate such increases of particle size and scattering in the following two sections.

The size spectra adjustment involves modification of the OPC-measured dry diameter of particles:

$$D_{dry,adj} = f(D_{dry})D_{dry} \tag{6}$$

where $f(D_{dry})$ is the *size-dependent* scaling factor obtained from theoretical response calculations by extending well-established approaches for correcting the OPC-derived size distributions [31,32,35]. In our work we take advantage of available AMS and SP2 measurements (Section 3) for estimating the complex RI (Section 4.2), and thus our approach can be applied to both non-absorbing and absorbing aerosol.

The original OPC-derived and corrected dry size distributions are related as

$$\frac{dN}{d \log D_{dry,adj}} = \frac{dN}{d \log D_{dry}} \frac{d \log D_{dry}}{d \log D_{dry,adj}} \tag{7}$$

In other words, the *size-dependent* correction (Eq. 6) modifies the original OPC-derived size spectra in two ways by (1) changing bin boundaries (horizontal shifting; replacement of D_{dry} with $D_{dry,adj}$) and (2) scaling of the normalized number concentration (vertical shifting; term $d \log D_{dry} / d \log D_{dry,adj}$).

The increase of particle diameter due to the water uptake is expressed as:

$$D_{wet} = HGF_{mix}(RH)D_{dry} \tag{8a}$$

$$D_{wet,adj} = HGF_{mix}(RH)D_{dry,adj} \tag{8b}$$

where the *size-independent* $HGF_{mix}(RH)$ is calculated from the chemical composition measurements (Section 4.1).

The corresponding dry and wet size distributions are related by the following equations

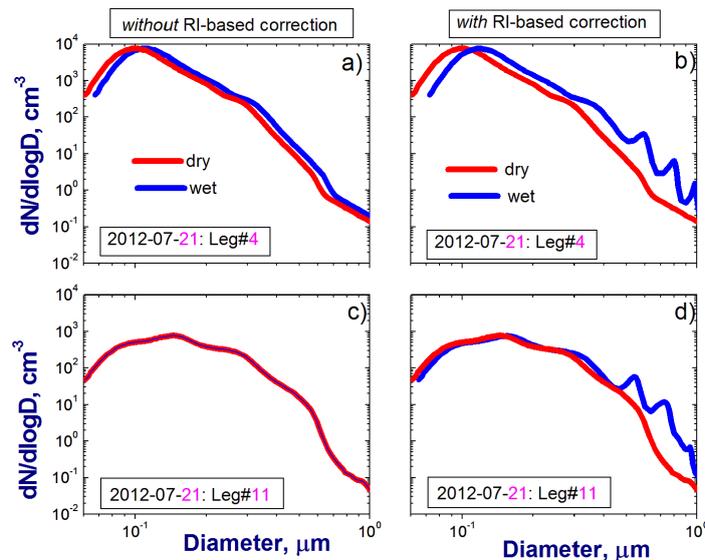

$$\frac{dN}{d \log D_{wet}} = \frac{dN}{d \log D_{dry}} \frac{d \log D_{dry}}{d \log D_{wet}} = \frac{dN}{d \log D_{dry}} \tag{9a}$$

$$\frac{dN}{d \log D_{wet,adj}} = \frac{dN}{d \log D_{dry,adj}} \frac{d \log D_{dry,adj}}{d \log D_{wet,adj}} = \frac{dN}{d \log D_{dry,adj}} \quad (9b)$$

378 Note that functions in Equation 9 (left-hand versus right-hand side) have different arguments; for
 379 example, $dN(D_{wet})/d \log D_{wet}$ (Equation 9a; left-hand side) and $dN(D_{dry})/d \log D_{dry}$ (Equation 9a;
 380 right-hand side). In comparison with the *size-dependent* scaling factor (Equation 6), the *size-*
 381 *independent* adjustment (Equation 8) associated with water uptake modifies the original OPC-derived
 382 size spectra by changing bin boundaries only (horizontal shifting; e.g., replacement of D_{dry} with D_{wet} ;
 383 Equation 9a); this adjustment does not cause the vertical scaling of the normalized number
 384 concentration (Equation 7 versus Equation 9).

385 To illustrate the conversion of the measured dry size distribution into the corresponding wet size
 386 spectra (Equations 8a and 9a), we select two flight legs with high ($RH \sim 78\%$) and low ($RH \sim 5\%$) values
 387 of relative humidity (Figure 5a). The RH -related increase of particle size results in the horizontal
 388 shifting of the size distribution (wet size spectra versus dry size spectra) and this shifting is seen for the
 389 humid conditions (Figure 7a versus Figure 7c). Since the theoretical response curves are multivalued
 390 for a resonance region (particle diameter $> 0.4 \mu\text{m}$) (Appendix C), the adjusted size distributions
 391 obtained at ambient RH with the *size-dependent* scaling factor (Equations 8b and 9b) exhibit a
 392 “bumpy” behavior for this region as well (Figures 7b,d).

393 **Figure 7.** Example of size distributions obtained for two FLs (July 21, 2012) with high
 394 (a,b) and low (c,d) values of ambient RH , respectively. Measured dry size distributions
 395 (red) are converted into their wet counterparts (blue) without (a,c) and with (b,d) the size-
 396 dependent scaling factor.

397

398 **4.3. Scattering Coefficient Calculations**

399 We calculate the ambient total scattering coefficient using both the ambient complex RI with real
 400 (n_{wet}) and imaginary (k_{wet}) parts (e.g., Figures 6a,b) and the ambient size distributions (e.g., Figures
 401 7b,d). The calculations of total scattering coefficients $\sigma_{mod,org}$ and $\sigma_{mod,adj}$ are performed for ambient

size distributions obtained without ($dN/d \log D_{wet}$) and with ($dN/d \log D_{wet,adj}$) the RI-based correction, respectively. Recall the RI is obtained at a single wavelength (0.55 μm). Results from previous studies [61,62] suggest that the spectral variability of the real part of RI is quite small within the visible spectral range considered here (0.45-0.7 μm). Therefore, the obtained real RI (0.55 μm) is likely representative for this spectral range and it can be applied to calculate the spectrally-resolved total scattering coefficient of weakly-absorbing aerosol. Note that the values of the imaginary part of RI at 0.55 μm wavelength are quite small (Figure 6b) and thus they represent weakly-absorbing aerosol. For such aerosol, the total scattering is only slightly affected by changes of the imaginary part of RI [61,62]; therefore its spectral dependence can be ignored for the dataset considered here. We perform calculations of the total scattering at three wavelengths (0.45, 0.55, 0.7 μm) using the same complex RI obtained at 0.55 μm wavelength.

Our calculations are based on the Mie code developed by *Barber and Hill* [63] assuming that particles are homogeneous spheres and effective values of the complex RI are size-independent (particles are assumed to be a homogeneous internal mixture; Section 4.2). Note that other computational methods should be applied to calculate optical properties of particles with inhomogeneous internal mixing and aggregate morphology [64] although the influence of the internal mixing and particle geometry on the total scattering is quite small for submicron particles [20,65,66]. We calculate the total scattering coefficients using the original and corrected size distributions with different cut-offs (1- and 2- μm). Large uncertainties (up to 50%) of the measured total scattering associated with coarse mode particles (particle diameter > 1 μm) [55], the limited size range of chemical composition data (particle diameter <1.0 μm) (Section 2), and small (<7% on average) relative contribution of coarse mode particles to the scattering coefficient (Appendix B) are the three main factors that led to the selected cut-offs. Note that there is a small difference (~2% on average) between total scattering values calculated for the 1- and 2- μm cut-offs (Appendix B), mainly due to the small fraction of supermicron particles for FLs considered here. Below we show the ambient scattering coefficients ($\sigma_{mod,org}$ and $\sigma_{mod,adj}$) calculated with the 2- μm cut-off only.

Uncertainties for the calculated scattering coefficient are associated mainly with ambiguities of the required inputs (ambient size distribution and complex RI) and model assumptions (homogeneous internal mixture). According to previous studies with similar model inputs [67], the uncertainties for the calculated dry total scattering are about 20%. Although assumptions associated with the hygroscopic growth factor estimation (Section 4.1) are likely to introduce additional ambiguities associated with the required inputs, we assume that the uncertainties obtained earlier for the dry scattering (20%) are also representative (at least as a lower limit) for the ambient total scattering considered in our study. The influence of the uncertainties mentioned above on agreement between the observed and calculated values at ambient conditions is considered in the next section.

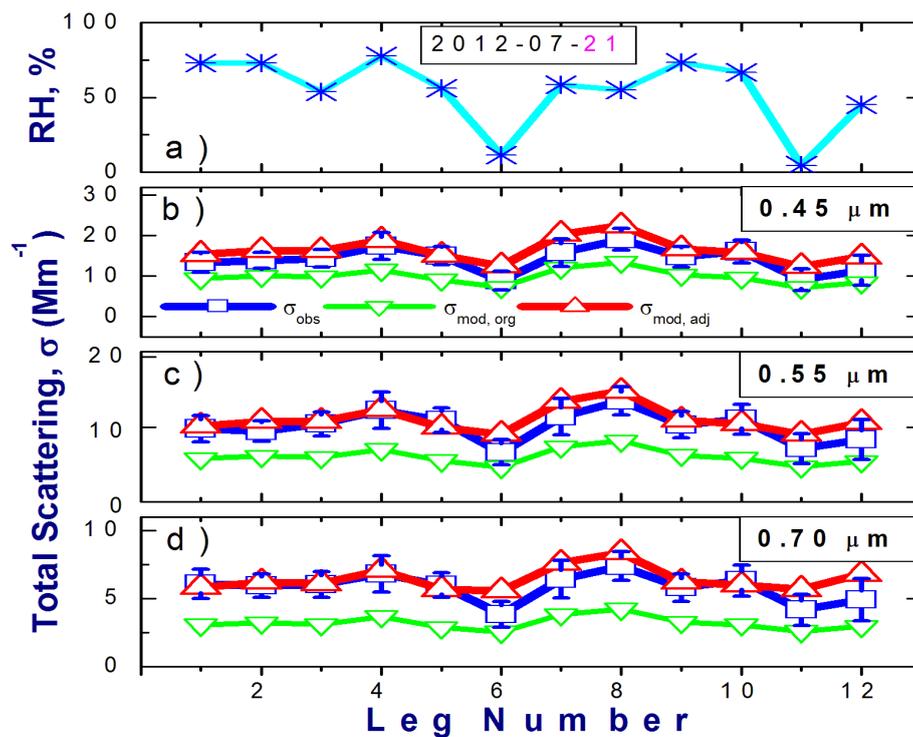

5. Results

This Section outlines the comparison component of our framework for an airborne optical closure experiment (Figure 1; bottom panel) and includes time series and statistics of the observed and calculated total scattering coefficients at ambient conditions. This Section is designed to address

442 questions 1 (level of agreement for “complete” dataset) and 2 (level of agreement for “incomplete”
 443 dataset given that the impact of chemical composition data on improved size spectra is ignored).

444 Let us start with the time series (Figure 8). The total modeled scattering $\sigma_{mod,org}$ calculated for the
 445 original size distribution substantially underestimates the observed scattering σ_{obs} for the majority of
 446 FLs considered on July 21, 2012. In contrast to $\sigma_{mod,org}$, the total scattering $\sigma_{mod,adj}$ calculated for the
 447 adjusted size distribution matches the observed scattering σ_{obs} reasonably well.

448 **Figure 8.** Ambient RH (a) and spectral values (b,c,d) of the total scattering coefficient
 449 measured (blue) and calculated for the original (green) and RI-based adjusted (red) size
 450 distributions for twelve FLs on July 21, 2012 at three wavelengths: (b) 0.45, (c) 0.55 and
 451 (d) 0.70 μm . Error bars represent uncertainties of measured scattering coefficient.

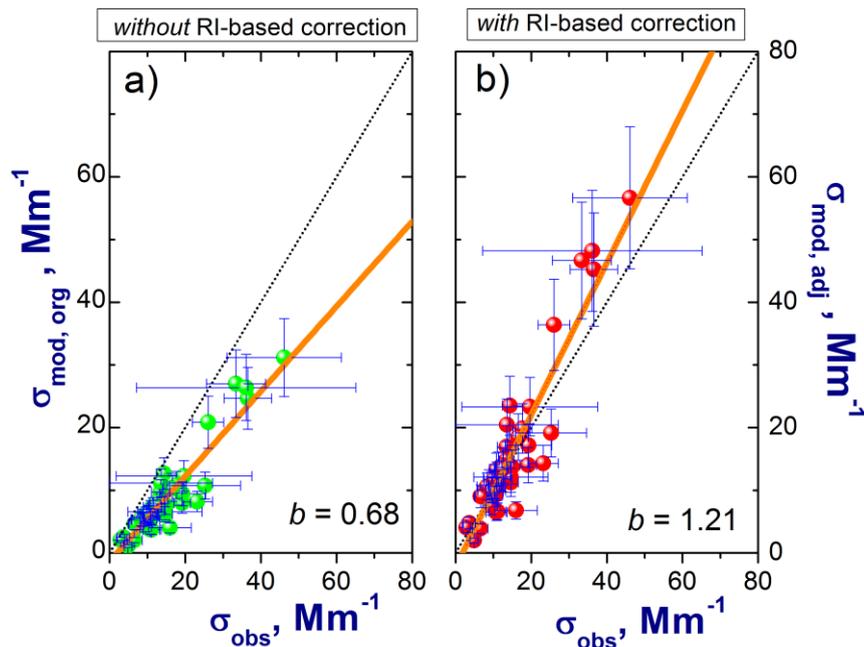

452 The differences in Figure 8 between calculated ($\sigma_{mod,org}$ and $\sigma_{mod,adj}$) and observed (σ_{obs}) scattering
 453 illustrate three main points. First, the observed scattering σ_{obs} tends to follow the ambient RH
 454 variations. For example, the lowest values of σ_{obs} occurred for dry conditions (FL numbers 6 and 11,
 455 where $RH < 10\%$). Second, inclusion of the hygroscopic growth of particles associated with water
 456 uptake alone (Section 4.3) is not sufficient for matching the observed ambient scattering ($\sigma_{mod,org}$
 457 versus σ_{obs}). In addition to the hygroscopic growth, application of the RI-based correction to the dry
 458 size distributions measured by the OPCs (Section 4.3) is required ($\sigma_{mod,adj}$ versus σ_{obs}). Finally, the
 459 calculated scattering $\sigma_{mod,adj}$ reproduces reasonably well the observed scattering σ_{obs} at all three
 460 wavelengths considered here (0.45, 0.55 and 0.70 μm), suggesting that our assumption of a spectrally-
 461 independent RI seems reasonable for the weakly-absorbing aerosol sampled during the TCAP flights.
 462

463 The substantial underestimation of $\sigma_{mod,org}$ versus σ_{obs} noticeable in Figure 8 is more obvious in
 464 the scatterplot of all considered TCAP FLs shown in Figure 9a. Since both the measured and
 465

466 calculated scattering can exhibit large uncertainties, the bivariate weighted method [68] is used to find
 467 the best linear fit. This method owes its popularity [69,70] to its versatility, robustness and ability to
 468 use uncertainties of both x and y variables to find the slope and intercept of a best fit straight line to the
 469 data [71]; additionally, standard errors of the slope and intercept may be estimated.

470 The slope of the corresponding linear regression fit is quite small (0.68). The slope increases from
 471 0.68 to 1.21 when the RI-based correction is applied to the OPC-derived size distributions (Figure 9a
 472 versus Figure 9b). There are 4 points with large observed values of scattering coefficient ($\sigma_{obs} > 30$
 473 Mm^{-1} , Figure 9). Close examination reveals that these points represent either large values of *RH*
 474 ($>67\%$) or highly inhomogeneous FLs (standard deviation of $\sigma_{obs} \sim 30 Mm^{-1}$). Removal of these
 475 points reduces slightly the slope (from 0.68 to 0.65, Figure 9a; and from 1.21 to 1.17, Figure 9b) and
 476 increases the intercept (from -1.30 to -1.11, Figure 9a; and from -2.25 to -1.91, Figure 9b). Also, such
 477 removal reduces the difference between the mean values of σ_{obs} and $\sigma_{mod,adj}$ considerably (roughly
 478 from 10% to 0.5%), while having little effect on the discrepancy between the mean values of σ_{obs} and
 479 σ_{mod} (about 40%).

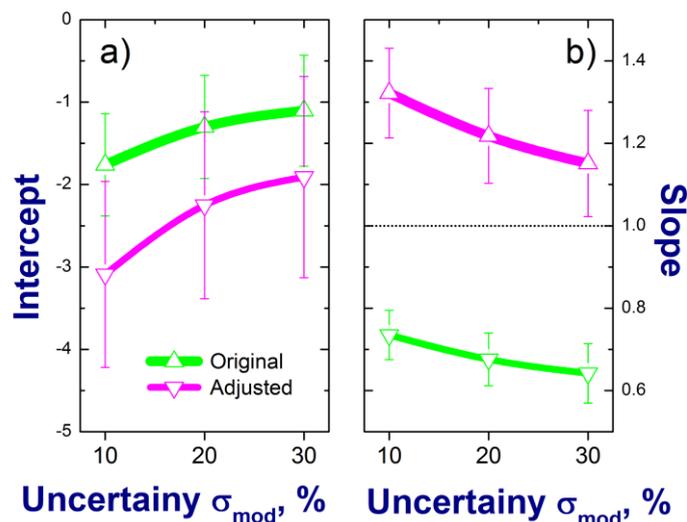

480 **Figure 9.** Comparison of the ambient total scattering observed (σ_{obs}) with ambient total
 481 scattering calculated (σ_{mod}) for the original (a) and adjusted (b) size distributions at
 482 0.55 μm wavelength for all TCAP FLs. Here *b* is the slope of the linear regression fits to the data (straight orange lines). Error bars represent uncertainties of measured (Section 3)
 483 and calculated (Section 4.4) scattering coefficients.
 484

485 Similar changes of parameters (slope and intercept) obtained with the bivariate weighted method
 486 can be achieved by increasing the uncertainties of the calculated scattering coefficient but keeping
 487 uncertainties of the observed scattering the same (Figure 10). These changes are mostly caused by the
 488 influence of four points with large values of the observed/calculated scattering coefficient on the
 489 parameters of fitting line. The influence of these points decreases when assumed uncertainties of the
 490
 491

492 calculated scattering are increased. Note that the assumed uncertainties (20%) of the calculated
 493 scattering represent dry conditions (Section 4) and thus, they likely are underestimated for FLs with
 494 moderate and high RHs (e.g., due to inaccurate treatment of the RH dependence of the HGF_{mix} and its
 495 components).

496 **Figure 10.** Intercept (a) and slope (b) of the linear regression fits (e.g., **Figure 9**) as a
 497 function of uncertainty for the ambient total scattering calculated for the original (without
 498 RI-based correction) and adjusted (with RI-based correction) size distributions. Error bars
 499 represent the standard errors of the displayed parameters (see text for details).

500
 501
 502 Comparable slopes for linear regression fits ($\sigma_{mod,adj}$ versus σ_{obs}) are obtained at the other two
 503 wavelengths (0.45 and 0.7 μm) (Table 2a,c). The weak spectral dependence of these slopes suggests
 504 that the complex RI obtained at 0.55 μm wavelength could be applied to estimate the spectrally-
 505 resolved total scattering within the mid-visible range (0.45-0.70 μm) reasonably well.
 506

507 **Table 2a.** Mean and Standard Deviation (StDv) of the observed (σ_{obs}) and calculated ($\sigma_{mod,org}$
 508 and $\sigma_{mod,adj}$) scattering coefficients at 0.45 μm wavelength obtained for all TCAP
 509 FLs. The corresponding intercept (a), slope (b), their standard errors (in parenthesis) and
 510 Root Mean Squared Error (RMSE) also are included. The RMSE is defined as the root
 511 mean squared difference between the observed and the calculated scattering coefficients.

	Mean	StDv	RMSE	a	b
σ_{obs}	20.05	12.26	-	-	-
$\sigma_{mod,org}$	13.70	10.42	7.49	-1.58 (0.80)	0.75 (0.06)
$\sigma_{mod,adj}$	22.75	17.09	7.10	-2.54 (1.33)	1.24 (0.10)

513 **Table 2b.** The same as Table 2a except for 0.55 μm wavelength.

	Mean	StDv	RMSE	<i>a</i>	<i>b</i>
σ_{obs}	14.85	8.98	-	-	-
$\sigma_{mod,org}$	8.80	6.78	6.99	-1.30 (0.63)	0.68 (0.06)
$\sigma_{mod,adj}$	15.89	12.17	5.01	-2.25 (1.13)	1.21 (0.11)

514 **Table 2c.** The same as Table 2a except for 0.70 μm wavelength.

	Mean	StDv	RMSE	<i>a</i>	<i>b</i>
σ_{obs}	8.73	5.28	-	-	-
$\sigma_{mod,org}$	4.87	3.78	4.61	-0.73 (0.45)	0.64 (0.07)
$\sigma_{mod,adj}$	9.77	7.57	3.85	-1.40 (0.90)	1.26 (0.15)

515
 516
 517 On average, the total scattering $\sigma_{mod,org}$ calculated for the original OPC-derived size distribution
 518 underestimates the observed scattering σ_{obs} substantially (Table 2). For example, underestimation of
 519 the mean value exceeds 40% at 0.55 μm wavelength. However, the total scattering $\sigma_{mod,adj}$ calculated
 520 for the RI-adjusted size distributions and the observed scattering σ_{obs} have comparable mean values
 521 (Table 2): the relative difference between them is quite small at three given wavelengths (about 13% at
 522 0.45 μm , 7% at 0.55 μm and 12% at 0.70 μm). In comparison with the mean values, the corresponding
 523 standard deviations are in moderate agreement ($\sim 40\%$). In addition to the basic statistics of mean and
 524 standard deviation, we calculate the corresponding Root Mean Squared Error (RMSE), which is
 525 defined as the root mean squared difference between the observed σ_{obs} and the calculated scattering
 526 coefficients in question. The corresponding RMSEs are about 7 and 5 Mm^{-1} for $\sigma_{mod,org}$ and $\sigma_{mod,adj}$ at
 527 0.55 μm wavelength, respectively. In other words, RMSE ($\sigma_{mod,org}$) overestimates RMSE ($\sigma_{mod,adj}$)
 528 noticeably ($\sim 30\%$).

529 Overall, the quantitative comparisons (Figure 9 and Table 2) demonstrate clearly that application of
 530 the RI-based correction improves the agreement between observed and calculated scattering
 531 coefficients, most notably in terms of the mean values and RMSE. Thus, our results are in line with
 532 findings from previous studies [31,32], which highlighted the importance of such RI-based corrections
 533 and suggested corresponding parameterizations for non-absorbing aerosol. These valuable
 534 parameterizations were designed assuming that the RI-based correction was a function of the real part
 535 of complex RI only. In our approach, both the real and imaginary parts of the complex RI are used as
 536 input and it thus can be applied for both non-absorbing and absorbing aerosol. It should be noted that
 537 the single-scattering albedo is moderate (0.93 ± 0.03) for the TCAP dataset considered here, therefore
 538 this dataset represents slightly-absorbing aerosol. Further studies are needed to examine the feasibility
 539 of our approach for improved calculations of total scattering/absorption for strongly-absorbing aerosol.

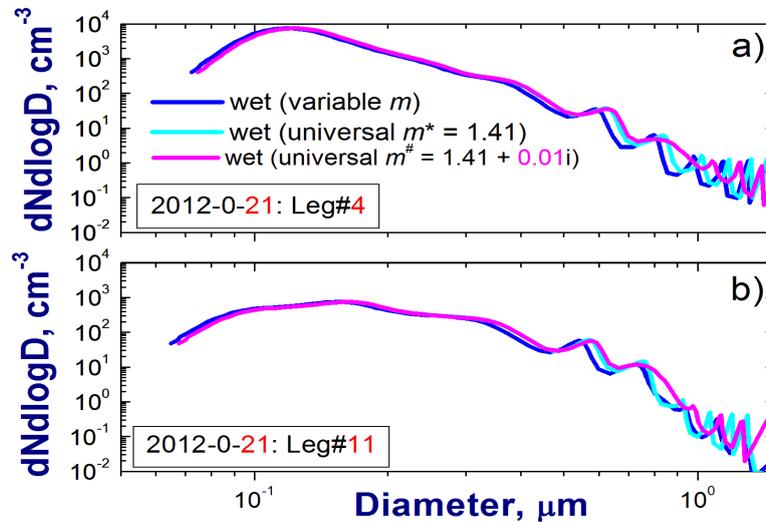

541 **6. Sensitivity study**

542 This Section is designed to supplement the previous one and to address question 3 (*level of*
543 *agreement for “incomplete” dataset given that a non-representative RI is used to correct size spectra*).
544 Note that we are able to use aerosol chemical composition data from the TCAP data set to obtain RI-
545 based corrections for each FL. However, as discussed in Section 1, a more common scenario is one
546 where chemical composition information is available only on a limited basis, or not at all. We wish to
547 investigate the sensitivity of the agreement between calculated and observed scattering to the assumed
548 RI value, particularly if the assumed RI is non-representative of the ambient aerosol. Further
549 motivation for this sensitivity test is the reported lack of agreement (outside the 30% measurement
550 uncertainty) between measured and calculated total scattering coefficients obtained recently for the
551 VOCALS-Rex marine atmosphere campaign [47] where a *universal* refractive index ($n^* = 1.41$ and
552 $k^* = 0$) derived from the entire VOCALS-Rex dataset [30] was used in adjusting observed PCASP
553 size distributions.

554 Given the strong sensitivity of VOCALS-Rex calculated scattering to size spectra uncertainties
555 [47], it can be hypothesized that the lack of agreement can be associated (at least partially) with the RI
556 specification and its strong impact on the adjusted size distributions. To confirm this hypothesis, we
557 calculate the total scattering from the TCAP data (Section 2) using the procedure previously employed
558 [47] for the VOCALS-Rex dataset. We emphasize that the main difference between their sensitivity-
559 driven procedure and our framework approach (Figure 1) is specification of the RI required for
560 adjusting the OPC-derived size spectra: an assumed universal real RI estimated implicitly from all
561 available aerosol composition measurements (sensitivity-driven procedure) versus a variable complex
562 RI estimated explicitly from the complementary chemical composition data (our framework approach,
563 Sections 3-5).

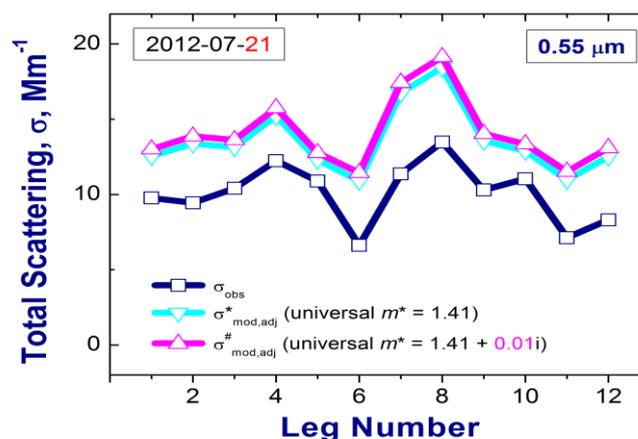

564 We apply an assumed universal RI ($n^* = 1.41$ and $k^* = 0$), equivalent to that used in VOCALS-Rex
565 analyses, to the entire TCAP dataset and compare the results with those from the variable RI estimated
566 from the TCAP AMS and SP2 data. This assumed RI might reasonably be adopted if TCAP had an
567 “incomplete” data set and we searched the literature for a reasonable universal RI applicable to
568 coastal/marine aerosols sampled aloft. Note that there is a noticeable difference between the assumed
569 RI and the estimated RI (Section 3) for many FLs. Compared with the variable RI, the use of the
570 *universal* RI in the size spectra adjustment increases the relative contribution of particles with
571 moderate diameter (within 0.4-0.8 μm range) (Figure 11), which scatter light in the visible spectral
572 range most effectively. This relative increase in optically important particles, in turn, is responsible for
573 a substantial rise of the calculated scattering coefficient (Figures 12,13a). As a result, the
574 corresponding mean value and RMSE (calculations based on variable RI versus the universal RI) are
575 enhanced by about 25% and 80%, respectively (Table 2b and Table 3). The mean value of the
576 calculated scattering coefficient (based on universal RI) overestimates the mean value of observed
577 scattering by about 35% (Table 3). This substantial overestimation (~35%) of the calculated scattering
578 coefficient: (1) confirms the hypothesis made above regarding the potential strong impact of the RI
579 specification on the calculated scattering and (2) suggests that use of a universal RI specification could
580 be one possible explanation for the lack of agreement noted in the VOCALS-Rex closure study [47].
581

582 **Figure 11.** Example of size distributions obtained for two FLs (July 21, 2012). Measured
 583 dry size distributions are converted into their wet counterparts with the size-dependent
 584 scaling factor calculated for universal (cyan, magenta) and variable (blue) RI. Two values
 585 of universal RI are assumed: $m^* = 1.41$ (cyan) for a non-absorbing aerosol and
 586 $m^\# = 1.41 + 0.01i$ (magenta) for an absorbing aerosol.

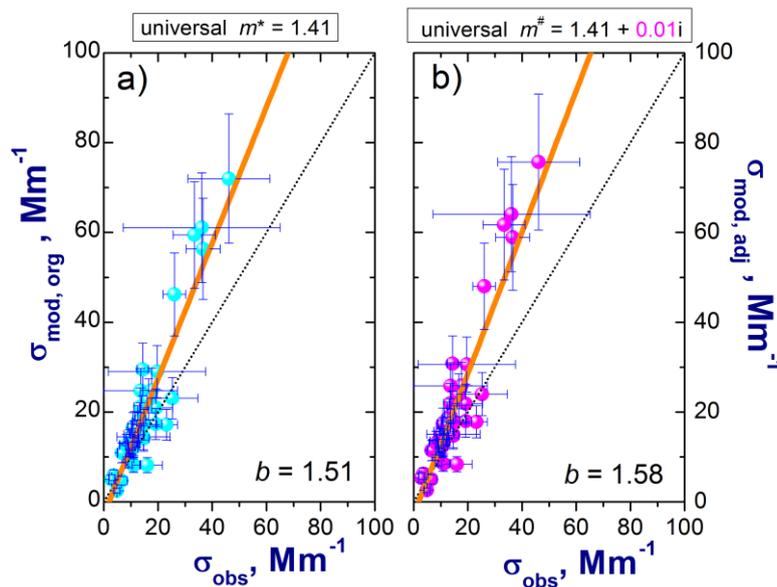

587 To examine the importance of the imaginary part of the complex RI in changing the adjusted size
 588 distribution and thereby in modifying the calculated scattering, we focus on the complex RI for an
 589 absorbing aerosol ($m^\#$). We assume that the corresponding universal complex RI has the real
 590 ($n^\# = 1.41$) and imaginary ($k^\# = 0.01$) parts. This selected value of the imaginary part ($k^\# = 0.01$)
 591 represents roughly the most frequent value observed under dry conditions during the TCAP campaign
 592 (Figure 6). Therefore, the imaginary part is the only difference between the complex RIs assumed for
 593 non-absorbing ($m^* = 1.41$) and absorbing ($m^\# = 1.41 + 0.01i$) aerosol.

595 **Figure 12.** Total scattering coefficient at 0.55 μm wavelength measured (navy blue) and
 596 calculated (cyan, magenta) for size distributions measured on July 21, 2012 and corrected
 597 using two assumed universal RIs: $m^* = 1.41$ (cyan) and $m^\# = 1.41 + 0.01i$ (magenta).

598
 599

Figure 13. Comparison of the ambient total scattering observed (σ_{obs}) with ambient total scattering calculated (σ_{mod}) for the size distributions adjusted with the universal RI. There are two values of assumed universal RI: $m^* = 1.41$ (a) and $m^\# = 1.41 + 0.01i$ (b). The observed and calculated values of total scattering are at 0.55 μm wavelength and all TCAP FLs. Here b is the slope of the linear regression fits to the data (straight orange lines). Error bars represent uncertainties of measured (Section 3) and calculated (Section 4.4) scattering coefficients.

Replacement of the imaginary part of the complex RI ($k^* = 0$ versus $k^\# = 0.01$) increases the difference between the corresponding size distributions (Figure 11; cyan curve versus magenta curve). Note that this replacement ($k^* = 0$ versus $k^\# = 0.01$) makes the adjusted size distributions “look smoother” within the resonance region (Figure 11; cyan curve versus magenta curve). The difference between the adjusted size distributions (Figure 11) is responsible for the difference between the corresponding total scattering coefficients (Figures 12,13 and Table 3). In particular, the replacement of the imaginary part of the complex RI ($k^* = 0$ versus $k^\# = 0.01$) increases the RMSE by about 10% (Table 3). Therefore, selection of an inappropriate imaginary part of the assumed complex RI can also increase the discrepancy between the calculated total scattering from the observed total scattering.

Table 3. The same as Table 2b except for the scattering coefficients $\sigma_{mod,adj}^*$ (middle row) and $\sigma_{mod,adj}^\#$ (bottom row) calculated for size distributions adjusted with two universal RIs $m^* = 1.41$ and $m^\# = 1.41 + 0.01i$, respectively.

	Mean	StDv	RMSE	a	b
σ_{obs}	14.85	8.98	-	-	-
$\sigma_{mod,adj}^*$	19.82	15.46	9.17	-2.85 (1.42)	1.51 (0.14)
$\sigma_{mod,adj}^\#$	20.67	16.19	10.20	-2.96 (1.48)	1.58 (0.15)

622 The results presented in this Section illustrate that selecting inappropriate values of the real part of
623 RI when adjusting OPC-derived size distributions in an optical closure study can cause substantial
624 *overestimation* of the calculated scattering coefficient. Moreover, selecting inappropriate values of the
625 imaginary part of RI can increase this overestimation noticeably, even for weakly absorbing aerosol.
626 Therefore, one should not expect closure studies based on such “incomplete” data sets to be as exact as
627 closure studies using “complete” data sets because of all the assumptions that must be made and the
628 high probability that the RI estimates based on these assumptions potentially will be inappropriate. The
629 error in RI estimates likely will be larger for aircraft sampling regimes because of the strong temporal
630 and spatial variability of aerosol sampled by research aircraft. When faced with an “incomplete” data
631 set, another possible approach is to use conventional iterative or optimization schemes, which apply a
632 set of assumed representative RI values for minimizing differences between the measured and
633 calculated aerosol properties of interest [35,41,72]. Such iterative or optimization schemes may
634 possibly improve the RI estimation relative to the approach of assuming a *universal* RI.
635

636 7. Summary

637 We extend methods for calculating total aerosol scattering at ambient *RH*, originally developed for
638 ground-based measurements [17,21,42] to the challenging situation of airborne measurements. The
639 importance of such extension is now widely recognized [6,46]. Our extended framework is suitable for
640 conducting optical closure studies using “complete” aircraft data sets, where “complete” means that
641 collocated and concurrent information on particle chemical composition is available. Our approach
642 takes advantage of the existing information on aerosol chemical constituents and explicitly uses it to
643 obtain improved ambient size spectra derived from complementary Optical Particle Counter (OPC)
644 data, and therefore to obtain improved estimates of the total scattering under ambient conditions with
645 low-to-moderate values of relative humidity ($RH < 80\%$).

646 To illustrate the performance of our approach, we use “complete” aerosol data collected by the
647 DOE G-1 aircraft during the recent the recent Two-Column Aerosol Project (TCAP;
648 <http://campaign.arm.gov/tcap/>) over the North Atlantic Ocean and US coastal region (Cape Cod,
649 Massachusetts). The integrated dataset collected by the G-1 aircraft includes: (1) size distributions
650 measured by three OPCs: an Ultra Sensitivity Aerosol Spectrometer (UHSAS; 0.06-1 μm), a Passive
651 Cavity Aerosol Spectrometer (PCASP; 0.1-3 μm) and a Cloud and Aerosol Spectrometer (CAS; 0.6-
652 >10 μm), (2) chemical composition data measured by an Aerosol Mass Spectrometer (AMS; 0.06-0.6
653 μm) and a Single Particle Soot Photometer (SP2; 0.06-0.6 μm) and (3) the dry total scattering
654 coefficient measured by TSI integrating nephelometer at three wavelengths (0.45, 0.55, 0.7 μm) and
655 $f(RH)$ measured with a humidification system at three *RH*s (near 45%, 65% and 90%) at a single
656 wavelength (0.525 μm). To illustrate the importance of the chemical composition data in the scattering
657 closure study, we also utilize “incomplete” aerosol data, where “incomplete” means that information
658 on particle chemical composition is not used to obtain the corrected ambient size spectra. The main
659 conclusions are organized along the three main questions we posed at the start of our study:
660

661 • Analysis based on using the “complete” dataset addresses our first question, namely: *What level*
662 *of agreement between the in-flight measured and calculated values of total scattering coefficient can*
663 *be achieved at ambient RH? We demonstrate that despite the well-known limitations of airborne*
664 *measurements and the assumptions required by our approach, we can obtain good agreement*
665 *between the observed and calculated scattering at three wavelengths (about 13% at 0.45 μm , 7%*
666 *at 0.55 μm , and 12% at 0.7 μm on average) using the RI-based correction for OPC-derived size*
667 *spectra and the best available chemical composition data for the RI estimation. We calculate the*
668 *total scattering coefficient from the combined size spectra (UHSAS, PCASP and CAS data) and*
669 *aerosol composition (AMS and SP2 data) at ambient conditions with a wide range of relative humidity*
670 *values (from 5% to 80%). These calculations involve several assumptions, such as the homogeneous*
671 *internal mixture assumption for estimating the hygroscopic growth factor and complex refractive index*
672 *(RI) at ambient conditions, and simplified specification of particle geometry (homogeneous spheres)*
673 *for Mie calculations.*

674
675 • Analysis based on using an “incomplete” dataset addresses our second question, namely: *What*
676 *is the effect of ignoring the influence of chemical composition data on this agreement? We illustrate*
677 *that ignoring the RI-based correction in the TCAP data can cause a substantial underestimation*
678 *(about 40% on average) of the ambient calculated scattering when noticeable discrepancies*
679 *between the actual RIs and those used for the OPC calibration have occurred. Our findings are in*
680 *harmony with previous studies, which have highlighted the importance of the RI-based correction and*
681 *have suggested its parameterization for non-absorbing aerosol assuming that the RI-based correction is*
682 *a function of real RI only [31,32]. In comparison with these important parameterizations, our approach*
683 *is more flexible in terms of available inputs (complex RI is estimated explicitly from the*
684 *complementary chemical composition data), and therefore in terms of the expected applications (both*
685 *non-absorbing and absorbing aerosol sampled by ground-based and airborne instruments).*

686
687 • Analysis based on using an “incomplete” dataset also addresses our third question, namely:
688 *How sensitive is this agreement to the assumed RI value, particularly if the assumed RI is non-*
689 *representative of the ambient aerosol? We illustrate in a sensitivity study that using a non-*
690 *representative universal RI instead of the actual RI can result in a large overestimation (about*
691 *35% on average) of the calculated total scattering at ambient RH, and this overestimation is*
692 *sensitive to specification of the imaginary part of RI, even for weakly-absorbing aerosol. This*
693 *sensitivity study suggests that the usefulness of assumptions required for universal RI estimation could*
694 *be marginal, particularly when applied to the strong temporal and spatial variability of aerosol sampled*
695 *by research aircraft. As a result, calculations of aerosol optical properties based on these assumptions*
696 *should be used with caution and other possible approaches should be considered to improve the RI*
697 *estimation. These possibilities include application of conventional iterative or optimization schemes*
698 *where a set of assumed representative RI values is used to minimize differences between the measured*
699 *and calculated aerosol properties of interest [35,41,66].*

700
701 To our knowledge, this work represents the first optical closure study that uses explicitly airborne
702 chemical composition measurements of both non-absorbing and absorbing aerosol components in

703 improving the OPC-derived size spectra. These measurements are employed to extend the capability of
 704 well-established methods originally developed for use with comprehensive ground-based
 705 measurements. Given the extended flexibility of these methods and the increasing availability of
 706 aerosol composition data collected from aircraft platforms, we expect that our approach can be
 707 successfully applied for improved understanding of a wide range of sophisticated processes and
 708 phenomena related to aerosols, including the time evolution of aerosol properties and dynamical
 709 aerosol-cloud interactions [73,74]. We further expect that closer agreement between measured and
 710 calculated aerosol properties, indicating the consistency of the observational dataset, will improve
 711 confidence in, and use of, such observational datasets in global and regional climate model
 712 evaluations. For example, appropriate adjustments to optical particle counter data are needed to better
 713 understand and evaluate predictions of cloud-aerosol interactions, since cloud condensation nuclei
 714 (CCN) calculations are dependent on the aerosol size distribution.

715 *Acknowledgments*

716 The ARM Aerial Facility team is gratefully acknowledged for collecting the aircraft data during
 717 TCAP which was supported by the Department of Energy (DOE) Office of Science Atmospheric
 718 Radiation Measurement (ARM) and Atmospheric System Research (ASR) Programs. The ARM Aerial
 719 Facility is an integral part of the DOE ARM Program. This research was supported by the ARM and
 720 ASR Programs. The Pacific Northwest National Laboratory is operated by Battelle Memorial Institute
 721 under contract DE-AC06-76RLO 1830. We appreciate valuable discussions with Elaine Chapman
 722 (PNNL) and thoughtful comments from two anonymous reviewers that helped improve our paper.

733 **Appendix A: Merging of Size Distributions**

734 This appendix explains how data from overlapping measurements from three instruments (UHSAS,
 735 PCASP, and CAS) are merged into the combined size distributions (Figure 3). The best estimate
 736 aerosol size distribution (\vec{N}) can be recovered from the merged raw counts (\vec{C}) if a Kernel function
 737 (\mathbf{R}) can first be quantified:

$$\vec{N}\mathbf{R} = \vec{C} \quad (\text{A1a})$$

738 or

$$\begin{bmatrix} n_1 \\ n_2 \\ \vdots \\ n_{j-1} \\ n_j \end{bmatrix} \begin{bmatrix} R_{UHSAS11} & R_{UHSAS12} & & & \\ R_{UHSAS21} & R_{UHSAS22} & & & \\ & & \ddots & & \\ & & & R_{CAS_{x-1,j-1}} & R_{CAS_{x-1,j}} \\ & & & R_{CAS_{x,j-1}} & R_{CAS_{x,j}} \end{bmatrix} = \begin{bmatrix} C_{UHSAS_1} \\ C_{UHSAS_2} \\ \vdots \\ C_{CAS_{x-1}} \\ C_{CAS_x} \end{bmatrix} \quad (A1b)$$

739

740 The raw counts are measured by the UHSAS, PCASP, and CAS. Furthermore, \mathbf{R} can be defined as
741

$$\mathbf{R}_{UHSAS_{i,j}} = Q_{UHSAS} t e_{UHSAS_{i,j}}, \mathbf{R}_{PCASP_{i,j}} = Q_{PCASP} t e_{PCASP_{i,j}}, \mathbf{R}_{CAS_{i,j}} = V_{TAS} A t e_{CAS_{i,j}} \quad (A2)$$

742

743 where Q , V_{TAS} , $e_{i,j}$, A and t are the flow, airspeed, collection efficiency for each probe, CAS laser
744 sample area and the data collection integration time, respectively. From calibrations we know the
745 collection efficiency ($e_{i,j}$) of each probe within a specified bin size, and the CAS laser sample area (A
746). The other variables Q (flow) and V_{TAS} (airspeed) are measured by the probes themselves during
747 operation.

748 To start the recovery process, a rough estimate of \bar{N} has to be provided. The size distribution
749 values $dN/d \log D_p$ for UHSAS, CAS, PCASP are first interpolated to the same bin space. The
750 concentration values from the UHSAS, CAS, and or PCASP that overlap in the same bin are averaged
751 together then converted back to dN by multiplying by the $d \log D_p$ value for that bin. Using the
752 estimation for \bar{N} , Twomey smoothing is started. The initial number distribution is smoothed until the
753 roughness of the solution has decreased to a set value, normally around 0.96. Roughness of the
754 solution is measured by the average value of the second derivative. This initial trial solution is then
755 ingested into a loop which continues until either the roughness of the solution has decreased below a
756 set limit (typically 0.98), the goodness of the fit decreases, or the maximum number of iterations has
757 been reached. After the loop successfully exits the resulting number distribution is considered the best
758 estimate aerosol size distribution.

759

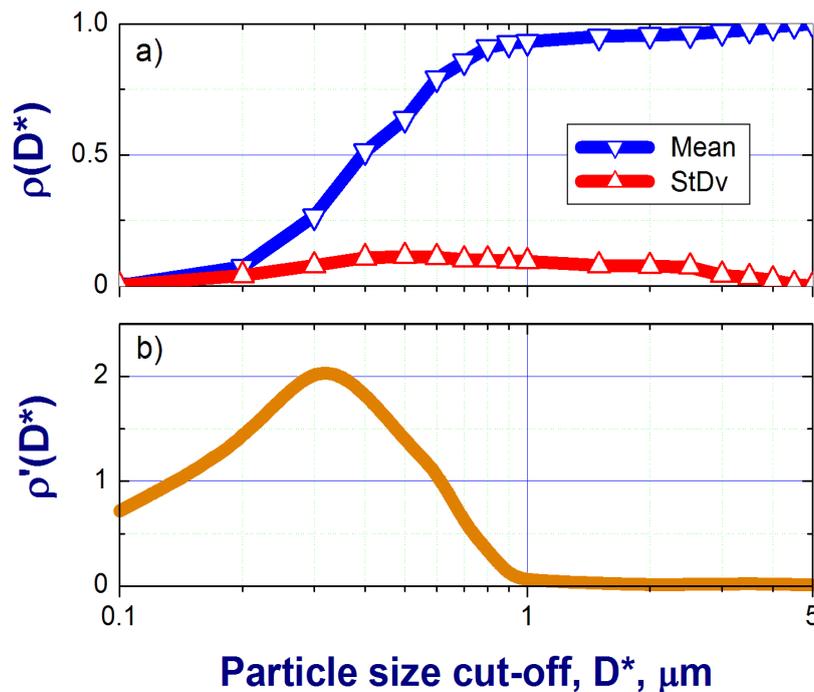

760 **Appendix B: Contributions from particles of different sizes to scattering**

761 To quantify contributions from particles of different sizes to the total scattering, we calculate the
762 ambient scattering coefficient $\sigma_{mod,adj} = \int_{D_{min}}^{D^*} C_{sca}(m, D) dN/d \log D d \log D$ at single wavelength
763 (0.55 μm), where C_{sca} is the scattering cross section, which is a function of particle diameter D and
764 size-independent complex refractive index (m ; Equation 5), $dN/d \log D$ is the ambient and corrected
765 number size distribution (Equation 9b), $D_{min} \sim 0.07 \mu m$ and D^* is an assumed cut-off (between 0.1 to
766 5 μm). Then we calculate normalized scattering coefficient $\rho(D^*) = \sigma_{mod,adj}(D^*) / \sigma_{mod,adj}(D^* = 5 \mu m)$,
767 which represents the relative contribution of particles with $D < D^*$ to the total scattering from all
768 particles smaller than 5 μm . Figure B1a shows the mean and standard deviation for $\rho(D^*)$ computed for
769 all 45 TCAP flight legs considered in this study (Section 3). Sub-micron particles clearly dominate the

770 total scattering in this case with $\rho(D^*)$ reaching about 0.93 and 0.96 for $D^* = 1 \mu m$ and $D^* = 2 \mu m$,
 771 respectively (Figure B1a). The obtained small (~7%, on average) contribution by the super-micron
 772 particles to the ambient scattering coefficient confirms the applicability of the simplified approach to
 773 the TCAP airborne data. For events where super-micron particles dominate, for example, aerosol
 774 plumes resulting from dust storms [75] or volcanic eruptions [35] application of the strict approach
 775 outlined above would be more relevant.

776 To further illustrate the relative contribution to $\sigma_{mod,adj}$ from different particle size ranges (for a
 777 given complex refractive index), we note that the above relation for the ambient scattering coefficient
 778 can be rearranged as $\sigma_{mod,adj} = \int_{D_{min}}^{D^*} (d\sigma_{mod,adj}(D)/dD)dD$. Using this rearranged relation, we calculate
 779 the derivative of the normalized scattering coefficient as $\rho'(D^*) = \sigma'_{mod,adj}(D^*)/\sigma_{mod,adj}(D^* = 5 \mu m)$,
 780 where $\sigma'_{mod,adj}(D) = d\sigma_{mod,adj}(D)/dD$. Figure B1b shows that on average particles in the size range
 781 between 0.3 and 0.4 μm contribute most strongly to the ambient scattering coefficient, while the
 782 corresponding contribution of particles in the “bumpy” region (particle sizes larger than 0.5 μm) is
 783 smaller.

784
 785 **Figure B1.** The normalized scattering coefficient (a) and its derivative (b) as a function of particle
 786 size cut-off. The blue line shows the mean for all TCAP flight legs and the red line represents the
 787 corresponding standard deviations.

 790

791 **Appendix C: Correction of OPC-derived Size Spectra**

792 This appendix includes details related to the calculations of the size-dependent theoretical response
 793 curves. The latter are required to obtain an adjusted dry diameter of particles (Equation 6) and the
 794 corresponding dry (Equation 7) and ambient (Equation 9b) size distributions using the OPC-derived

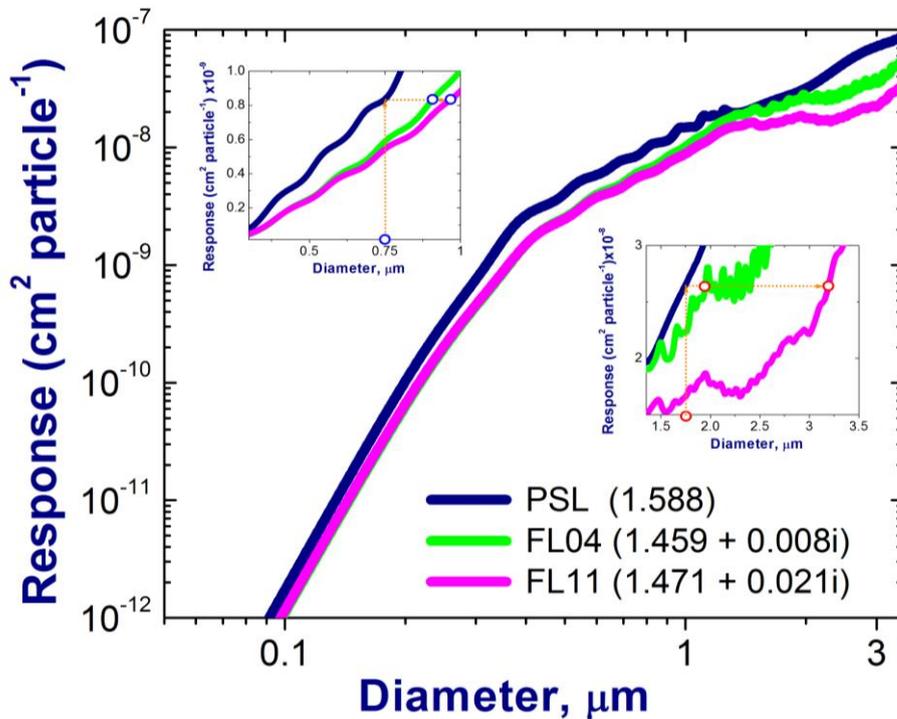

795 size spectra. Recall that during the OPC measurements individual particles are illuminated by a laser
796 beam and then the light scattered by the particles is collected over a large solid angle [33,34,35,76].
797 The wavelength of the illuminating light and solid angle limits are known properties of a given
798 detector [12]. For example, the UHSAS and PCASP collect side-scattered light (~35-135 degrees) at
799 0.6328 μm and 1.054 μm wavelength, respectively; while the CAS collects forward-scattered (~4-13
800 degrees) and back-scattered (~5-14 degrees) light at 0.685 μm wavelength. Therefore, strictly
801 speaking, the scaling factors should be calculated for each instrument independently using the
802 specified properties, and then the individual *corrected* size spectra (UHSAS, PCASP and CAS) used to
803 obtain the corresponding merged size distributions. We shall call this the “strict approach.” Another
804 potential approach could include the development of empirical relationships between the scattering
805 measured over the limited range of angles and the total scattering for given compositions and ambient
806 conditions. Such an “empirical approach” would not involve Mie calculations and therefore would
807 relax assumptions and data requirements for the RI-based corrections.

808 For our study, the individual *uncorrected* size spectra (UHSAS, PCASP and CAS) are combined to
809 obtain the corresponding merged size distributions (Section 3) and then these merged distributions are
810 corrected. We shall call this the “simplified approach.” The basis of this simplified approach is the
811 assumption that the properties of the PCASP (both the wavelength of the illuminating light and the
812 solid angle limits) are representative of all merged size distributions. Such a simplification is motivated
813 by the fact that the PCASP-derived size distributions represent particles in the 0.13-3 μm size range
814 (Section 2), which scatter light most effectively in the visible spectral range considered here (about
815 0.2-0.7 μm). It can therefore be expected that the PCASP-derived size distributions contribute most of
816 the total scattering measured by this airborne nephelometer.

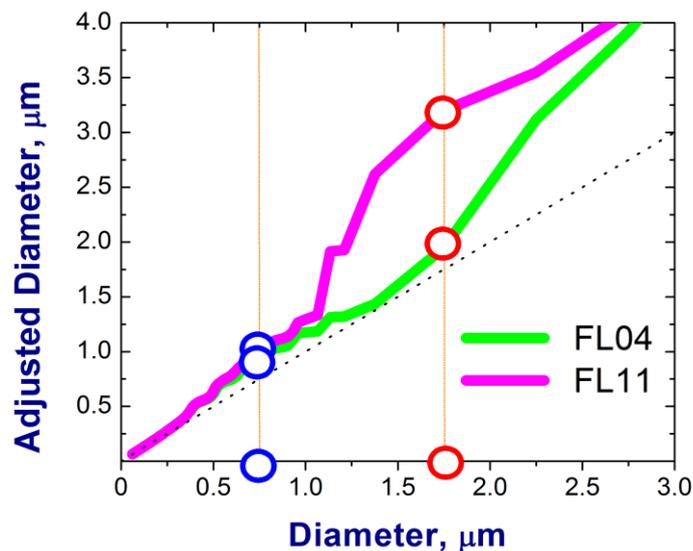

817 We apply the simplified approach to calculate the theoretical response curves (Figure C1) and
818 adjust particle diameters (Figure C2). Let us start with Figure C1. The first curve represents an
819 assumed “experimental” one, which would be obtained from laboratory calibrations with particles with
820 a known RI. Given that uncertainties of the experimental calibration are unknown, the “experimental”
821 curve is the smoothed version of the corresponding theoretical response curve. A polynomial
822 (curvilinear) regression model [77; pages 342-347] is applied to generate this smoothed version.
823 Similar smoothed versions have been used previously for different OPCs [35]. The second and third
824 curves represent low and high values of the imaginary part of RI obtained for two FLs (Figure 6b) and
825 illustrate two important points. First, the corresponding curves are comparable and “smooth” for
826 particles with diameter smaller than 0.75 μm ; (Figure C1; upper zoom-in panel). In contrast, the curves
827 are quite different and “bumpy” for large particles with diameter between 1.5 μm and 3.0 μm (Figure
828 C1; lower zoom-in panel). Second, the observed “bumpy” behavior is responsible for the well-known
829 multivalued issue, when particles with different diameter can produce the same response (Figure C1;
830 lower zoom-in panel, green curve). In the presented calculations, we assume that the corresponding
831 response is due to a particle with minimal diameter (Figure C1; lower zoom-in panel, red open circle
832 on green curve). The observed differences between the second and third curves (Figure C1) are
833 responsible for the corresponding differences between the adjusted diameters (Figure C2).

834
835

836 **Figure C1.** Example of theoretical response curves as a function of dry diameter (D_{dry})
 837 calculated for spherical particles and different values of complex RI. These values
 838 represent polystyrene latex spheres (PSL; navy blue) and those calculated for two FLs
 839 (FL=4, green; FL=11, magenta; July 21, 2012) from chemical composition measurements
 840 under dry conditions. Two complementary zoom-in versions of the calculated response
 841 curves are also included to illustrate that these curves may exhibit “smooth” and “bumpy”
 842 behavior for different ranges of diameter (see text for details).

843 **Figure C2.** Adjusted dry diameter ($D_{dry,adj}$) as a function of original dry diameter (D_{dry})
 844 obtained for two FLs (FL=4, green; FL=11, magenta; July 21, 2012) from the calculated
 845 response curves (Figure C1).
