Abstract

The BRAHMS collaboration is requesting a 2-3 week pp run at 62.4 GeV to complete and augment the heavy ion program of AuAu and Cu-Cu at this same energy. These data are crucial for deducing the nuclear modification factors $R_{AA}$ and in Au-Au and Cu-Cu collisions at 62.4 GeV and quantifying the suppression for identified mesons at intermediate $p_T$ at both mid-rapidity and at large rapidity. At the same time we propose to make measurement of $A_N$ of $\pi^-$ and $\pi^+$ in transversely polarized pp collisions at large $x_F (\approx 0.5)$. A measurement of $A_N$ at this energy will bridge the measurements of this quantity from FNAL to full RHIC energy.

1 pp reference spectra at 62.4 GeV

The BRAHMS physics program in the first 5 RHIC runs has mapped out global features of particle production in rapidity and $p_T$ for Au-Au at 130, and 200 GeV, in d-Au at 200 GeV, Cu-Cu at 200 and 62.4 GeV, and pp at 200 GeV. The evidence gathered from the first 4 runs has been evaluated and presented in the BRAHMS whitepaper[1]. Nuclear modification factors for all heavy ion systems have been studied in a wide range of rapidity ($\eta = 0 - 3.5$) at an intermediate $p_T$ range up to 4 GeV/c. These data are used to understand the rapidity dependence of jet quenching and gluon saturation, and thus is a tool to disentangle the physical processes involved. The large suppression in AA
systems is nearly constant with rapidity for both $h^{\pm}$ as well as for identified pions This is certainly surprising, and indicates that the color dense medium is extended in rapidity. The precise interpretation of these results is complicated by competing effects, namely, effects of a decreasing $dN/d\eta$, a change in the underlying reference pp spectrum, and possible entrance channels effects related to gluon saturation in AA.

Figure 1: Nuclear modification factor $R_{CP}$ for charged hadrons at pseudorapidities $\eta = 0$, 1, and 3. Statistical errors are shown with error bars. Each panel shows a given collisions system, namely Au-Au and 200 GeV, Au-Au at 62.4 GeV and Cu-Cu at 62.4 GeV.

A recent analysis[2] of Au-Au and Cu-Cu data at 62.4 GeV has revealed a similar trend as at the full RHIC energy. The data shown in Fig.1 summarizes the BRAHMS result on $R_{CP}$ at this energy for charged hadrons. The $R_{CP}$ was used, even though this quantity does not reflect the suppression as well as $R_{AA}$ due to the presence of common effects in central and peripheral collisions. These data shows that for all collisions systems, and at the lower energy of 62.4 GeV a significant suppression is observed at intermediate $p_T$ at large rapidities. In order to obtain the $R_{AA}$ from the data collected in both the Au-Au and Cu-Cu data from run 4 and run 5, respectively it is imperative to obtain spectra for identified charged hadrons at $\eta = 2.5$ and 3 (8 and 4 degrees). The existing data at lower ISR energies are very sparse at forward rapidities[4]. Further more been demonstrated[5] that pQCD does not provide an adequate description at forward rapidities. Thus experimental data is a must. A distinct difference between pions and baryons (protons) has also been observed at all rapidities, with the baryons not being suppressed. Therefore sufficient statistics is needed to measure both pions and protons at these rapidities.

Even at mid-rapidity where data from several ISR experiments exist for charged and neutral pions the status of reference data is quite uncertain as described in [3]. BRAHMS major data sets for Au-Au and Cu-Cu collisions
at 62.4 GeV is taken at $\eta = 1$ where additional transformations of the ISR data from mid-rapidity is needed to construct a reference spectrum. Henceforth direct measurements of the hadrons spectra at $\eta=1$ in pp at 62.4 GeV with the BRAHMS spectrometers would very much enhance the understanding of the nuclear suppression at 62.4 GeV which an important step between SPS and maximum RHIC energies.

2 Transversely Polarized pp at 62.4 GeV

Measurements of transverse spin asymmetries in pp collisions at forward angles may reveal information on the internal spinstructure of the proton, in particular on the orbital angular momenta of the quarks. Large asymmetries has been reported for charged pion production at $\sqrt{s_{NN}} = 19$ GeV [6], and for $\pi^0$ at 200 GeV[7]. The BRAHMS data from the previous RHIC run aquiered a small sample of data at $0.15 < x_F < 0.35$ for $\pi^\pm$ transverse asymmetry[8] The measured raw asymmetries corrected for the beam polarization is shown in Fig. 3 for $\pi^-$ and $\pi^+$. The $\pi^+$ asymmetries are positive while the $\pi^-$ are negative i.e. the same sign dependence as seen in the E704 data at lower energy.

The just completed run-5 resulted in a much large sample and allows an extension of the measurements to higher $x_F$ and $p_T$ with better both systematic and statistical uncertainties.

![Figure 2: Analyzing power $A_N$ for $\pi^+$ and $\pi^-$.](image)

The data at full energy only cover up to a moderate $x_F$ of 0.3-0.35, but in a range of $p_T$ value where pQCD may be appropriate. At the lower beam energy the BRAHMS forward spectrometer spans the complete range of $x_F$, but to make a measurement in a reasonable short time the $x_F$-range may be limited to up to about 0.5. Based on the extrapolations from lower and higher energies a fairly large asymmetry is expected possibly around 20 – 30% so the statistics needed will also be moderate.
3 Request

In this section we outline what the requirements to delivered beam is to achieve the physics outlined above. The C-A department have given the information that an average luminosity of $2 \times 10^3 \text{cm}^2 \text{s}^{-1}$ can be achieved at 62.4 GeV with 3 collision points at $\beta^* = 3.5$. This corresponds to a mean luminosity of 0.7 pb$^{-1}$ per week. For the $A_N$ measurements the beam has to be polarized transversely. It is assumed that a polarization of 50% or better can be achieved. This was obtained in RUN-5 and should be better with the operation of the cold snake in AGS.

The key measurements to be made includes for the forward spectrometer.

- 4 degrees 3 field settings 2 polarities.
- 8 degrees 1 field settings 2 polarities.
- 2.3 degrees 1 field setting 2 polarities.
- simultaneous with these measurements the MRS at 45 degrees ($\eta \approx 1$).

The aim is to get comparable statistics as for the Cu-Cu and Au-Au data at the same settings. Figs. 3 and 3 shows examples of the yields that can be obtained in a nominal 24 hours period with the standard assumptions of machine and experiment up-time and efficiency.

**Figure 3:** Estimate Collected Yield for $\pi^-$ per 24 hours for $\pi^-$ at 4 degree at half field.

The measurement plan with contingency and initial setup time translate into 16 days of physics beamtime or an equivalent delivered luminosity of 1.6 pb$^{-1}$.
